study a control group that is ethnically matched to the disease group. This is a major issue generally in genetic case-control studies, and several approaches to control for this have been proposed⁶⁶ including the use of panels of genetic markers that specifically reflect ethnic background.⁶⁷ These methodologies for correcting for underlying population are now widely accepted and indeed are often required for publication in leading genetics journals. It is generally not adequate to accept self-reported ethnicity as a basis for matching cases and controls.

Finally, a third (and common) reason for observing a genetic association is that the causative gene is actually in linkage disequilibrium with the marker allele being tested, be it a SNP or a particular HLA variant. Linkage disequilibrium is discussed in greater detail in the next section and refers to the fact that genetic variants at adjacent loci often tend to be found together more frequently than expected by chance. Linkage disequilibrium over long distances is a particularly prominent feature of the HLA region, particularly for certain haplotypes.^{68,69} A good example of how HLA associations can reflect linkage disequilibrium with a gene that is functionally unrelated to HLA is hemochromatosis. Early studies showed that certain HLA class I alleles such as HLA-A3 were highly associated with this disorder. However, it is now clear that the causative gene, *HFE*, is actually more than 3 million base pairs distant from the HLA-A locus (toward the telomere in Figure 21-4). The HLA-A3 association is observed simply because the *HFE* C282Y allele (causative for hemochromatosis) is frequently found on the same haplotype (see Table 21-1) as the HLA-A3 allele in many white populations.

Because there are a number of genes with immunologic function within the MHC complex that may themselves be directly involved in predisposing to autoimmunity, these loci must always be considered as possible causative genes when considering the significance of a new HLA association with rheumatic disease. Indeed, recent studies of autoimmune diseases indicate that multiple genes within the MHC can contribute independently to disease risk. In the case of RA, a number of studies have indicated that a separate locus in the central MHC may associate with the disease, independently of the HLA-DRB1 locus.⁷⁰⁻⁷² In addition, there is evidence that genes in the class I region may influence the risk conferred by certain HLA-DRB1*0404 haplotypes⁷² or may interact with other non-MHC genes.⁷³ Similar analyses in type 1 diabetes,⁷⁴ lupus^{75,76} juvenile arthritis,^{77,78} multiple sclerosis,⁷⁹ and myasthenia⁸⁰ all point to the fact that multiple different genes within the MHC can contribute to disease susceptibility. This issue is currently a major focus of research efforts in autoimmune diseases, and it is highly likely that additional risk genes in the MHC will be defined in the next few years using the dense SNP mapping techniques discussed in the following sections.

Linkage Disequilibrium

The concept of linkage disequilibrium is central to understanding the significance of any genetic association including HLA associations with disease. Linkage disequilibrium exists when the frequency of two alleles occurring together on the same haplotype exceeds that predicted by chance. For example, a common MHC haplotype that exhibits

linkage disequilibrium in the white population carries a certain combination of alleles, A*0101-B*0801-DRB1*03011, commonly referred to as the A1-B8-DR3 haplotype, and more recently designated the “8.1” haplotype.⁶⁸ This haplotype is present in about 9% of the Danish population, a typical white Northern European group. To understand why this reflects the presence of linkage disequilibrium, consider the fact that the A1 allele is present in 17% of Danes and the B8 allele is present in 12.7% of Danes. They could be expected to be found together only $12.7\% \times 17\% = 2.1\%$ of the time, much less than what is observed (9%). This simple difference between the expected and observed association between alleles is a measure of linkage disequilibrium, known as *D*; in this case $D = (0.09 - 0.021) = 0.069$. Table 21-7 provides the general calculation of *D* for a simple two-locus, two-allele situation. Because the magnitude of *D* is strongly influenced by the relative frequencies of the various alleles, normalized measures of linkage disequilibrium are used in practice including *D'* and *r*², as described in Table 21-7.

It is useful to understand these measures of linkage disequilibrium because detailed maps of linkage disequilibrium are widely available online for the entire human genome, with easy-to-use visualization tools (see www.hapmap.org). The lower portion of Figure 21-6 shows a visualization of LD using the *D'* measure for a region around the *PTPN22* gene on chromosome 1. The *D'* value between any two markers is reflected by the heat map (red *D'* = 1; white *D'* = 0). In this case, linkage disequilibrium extends well

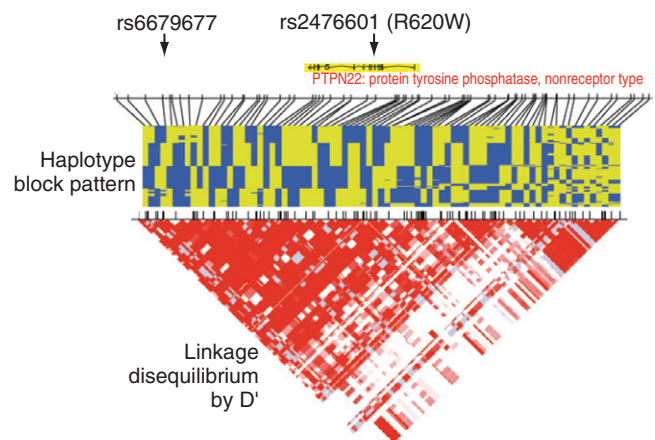

Figure 21-6 Map of the region around the *PTPN22* locus on chromosome 1p13 covering approximately 200,000 base pairs. The blue and yellow haplotype pattern in the central part of the figure was generated by looking at combinations of single nucleotide polymorphism (SNP) alleles in 90 white subjects from the HapMap Project. It is analogous to the presentation of linkage disequilibrium discussed in Table 21-7. Note that despite the large number of SNPs, a limited number of haplotype patterns are observed, generating a kind of bar code for each subject. The lower portion of the figure shows a heat map in which the intensity of red color reflects the degree of correlation (linkage disequilibrium [LD] measured by *D'*) among SNPs across the region (indicated by tick marks). Note that widely separated SNPs are highly correlated. Two markers associated with type 1 diabetes (and other autoimmune diseases) are shown at the top. Marker rs2476601 is likely to be the causative variant in this region and results in an amino acid change at codon 620. Note that another marker (rs6679677) nearly a distance of 100 kb also strongly associates with diabetes, emphasizing that it is difficult to assign the causative locus on the basis of associations alone when extensive linkage disequilibrium exists in a region.

Table 21-7 Measuring Linkage Disequilibrium

Consider a region of a chromosome with two adjacent loci, A and B. At each locus, there are two possible alleles, 1 and 2. There are four possible combinations of alleles, or haplotypes. These are shown below including a color bar representation and designations for the frequency of these haplotypes in the population.

A_1 — B_1		frequency = x_{11}
A_1 — B_2		frequency = x_{12}
A_2 — B_1		frequency = x_{21}
A_2 — B_2		frequency = x_{22}

Designate the allele frequencies at locus A as p_1 and p_2 .
Designate the allele frequencies at locus B as q_1 and q_2 .

Then

$$p_1 = x_{11} + x_{12}$$

$$p_2 = x_{21} + x_{22}$$

$$q_1 = x_{11} + x_{21}$$

$$q_2 = x_{12} + x_{22}$$

A simple measure of D is then calculated as $D = x_{11} - p_1 * q_1$. This value directly measures the difference between the observed haplotype frequency (in this case x_{11}) from that expected from random association of the alleles at each locus (in this case $p_1 * q_1$). For any allelic combination in a given dataset, the magnitude of D will be the same, although the sign (+ or -) may change according to the direction of the allelic association on the haplotypes.

A more standardized measure of D is more useful in practice and is designated D' . D' is the ratio of the observed D to the maximal (or minimal) possible value of D given the observed allele frequencies.

$$D' = \frac{D}{D_{max}} \text{ when } D \geq 0 \quad \text{and} \quad D' = \frac{D}{D_{min}} \text{ when } D < 0.$$

D' can therefore take on values between 0 and 1, and it is a measure of linkage disequilibrium that is normalized for variations in allele frequencies at the two loci.

Another useful measure of LD is the correlation coefficient, r^2 , between alleles at A and B. Like D' , the value of r^2 can also vary between 0 and 1. However, unlike D' , the value of r^2 is a more global measure of how alleles at the two loci are associated and is given by:

$$r = \frac{D}{\sqrt{p_1 p_2 q_1 q_2}}$$

When r^2 is = 1, there are only two possible haplotypes, and knowing the allele at locus A is completely predictive of the allele present at locus B. In this case, D' also = 1. However, D' can = 1 when $r^2 < 1$. In this case, there will only be three possible haplotypes in the population. If D' is < 1, there will be four haplotypes in the population. This is illustrated in the colored two-locus phased haplotype displays shown below.

A presentation of phased haplotypes similar to these is shown for the region around the *PTPN22* gene in Figure 21-6.

beyond *PTPN22* itself. Indeed, as indicated in the figure, the SNP marker rs6679677 was used by the Wellcome Trust Case Control Consortium (WTCCC) to detect the underlying association of RA with *PTPN22* even though this marker is 100kb distant from the causative SNP at rs2476601 within the *PTPN22* gene.

Three likely explanations for linkage disequilibrium (LD) exist. First, the population may have originated from a mixture of two populations, one of which had a high frequency of a particular haplotype. If this happened recently, there would not have been time (i.e., a sufficient number of generations) to randomize alleles at closely linked loci by recombination at meiosis. Inasmuch as human history is marked by large population migrations,⁸¹ it is

probable that population admixture explains many examples of linkage disequilibrium.

A second explanation, related to the first, rests on the observation that certain regions of the genome tend to exhibit relatively low levels of meiotic recombination for reasons related to the underlying genomic structure. Thus genetic variants within these regions tend to stay together on the same haplotype over many generations, even if haplotypes were introduced into a population in the distant past. The importance of this concept for understanding LD is still under active debate in the genetics community. A third explanation for LD posits that the alleles in linkage disequilibrium may be maintained together because of a selective advantage. For example, going back to the

A1-B8-DR3 haplotype mentioned earlier, one could postulate an advantage for immune defense when alleles on this haplotype are maintained and regulated together in the same individual. Although plausible, this hypothesis is difficult to prove for any particular haplotype.

Alternatives to the Case-Control Method for Detecting Disease Association

Family-based controls can also be used for doing genetic association studies. Consider the family shown in Figure 21-7. The affected child carries DR4 and DR3, each of which is inherited from one parent. The laws of mendelian inheritance specify that one DR haplotype from each parent is not inherited by any given offspring—in this example, DR2 in the father and DR5 in the mother. These two non-inherited haplotypes can be thought of as forming a genotype for a “control” individual. In this manner, issues of population stratification (see earlier) are eliminated because patients and controls are sampled from the identical (parental) gene pool. Falk and Rubinstein originally proposed this approach to disease association and called it the haplotype RR method.⁸² Its validity depends on a number of assumptions including that the genetic marker under study does not influence mating preference or the production of gametes.

An extension of this approach is called the transmission disequilibrium test (TDT).⁸³ Using the family in Figure 21-7, for a given heterozygous parent (such as the father carrying DR2, 4), there is a probability of 0.5 that any given allele, such as DR4, will be transmitted to the child. If the DR4 allele has no bearing on disease risk, the probability of transmission (T) to an affected child is equal to the probability of nontransmission (NT). This can be stated simply as $P(T|D) = P(NT|D)$, in which D indicates the presence of disease in the offspring. However, if the allele being examined is associated with disease risk, then $P(T|D) > P(NT|D)$. If large numbers of heterozygous parents with affected offspring are examined, transmission disequilibrium testing can establish an association between disease and the test allele compared with the (noninherited) control alleles. Although the TDT is an elegant solution to getting around the issue of population stratification, it is generally more expensive to collect and genotype trio families and the TDT has less statistical power than a standard case-control approach to association.

Figure 21-7 Family structure utilized for determination of haplotype relative risk. The affected child carries the DR3 and DR4 alleles. A fictitious “control” individual can be constructed from the noninherited DR2 and DR5 alleles and used for a relative risk calculation. Such families can also be utilized for transmission disequilibrium testing, as discussed in the text.

GENETICS IN THE ERA OF WHOLE GENOME ANALYSIS

As pointed out in the introduction, there has been an explosion in new genetic knowledge over the past few years and this is likely to continue for some time. A major foundation was laid by the completion of the Human Genome Project,^{84,85} which provided a draft reference sequence for the entire 3.2 billion base pairs of the human genome. Subsequently, the human HapMap Project⁸⁶ has provided a catalog of the common sequence variation across the human genome. There are now more than 30 million SNPs referenced for *Homo sapiens* in dbSNP, the online SNP reference database. In addition to SNPs, there are tens of thousands of variable numbers of tandem repeats (VNTRs), a common form of which is termed a *microsatellite*. Microsatellites have been used extensively for linkage analysis over the past decade.⁸⁷ Large insertions and deletions are also quite common across the genome,⁸⁸ some of which arise de novo,⁸⁹ providing yet another source of individual genetic variation that can be associated with human disease. Smaller insertions and deletions are just beginning to be cataloged, and thus the number of these genetic variants will grow substantially as more human genomes are fully sequenced.

Against this background of basic information about DNA variation, there has been sweeping technologic change, so it is now rather routine to obtain data on hundreds of thousands or even millions of SNP genotypes on many individuals in a matter of days,⁹⁰ and sequencing of the entire human genomes of large numbers of subjects has fast become a reality at sustainable costs. This in turn has provoked the development of sophisticated statistical approaches to large datasets, at the same time highlighting the need to integrate the genetic knowledge with clinical data in ways that are manageable and meaningful to researchers and ultimately to practitioners. Thus although the basic principles of association and linkage disequilibrium discussed earlier in the context of the HLA are still valid, the imminent availability of massive genetic datasets now mandate new, more efficient ways to store and analyze the data.

Another unsettled issue concerns the overall genetic “architecture” of human disease.⁹¹ Until recently, there has been an assumption that common allelic variants are likely to account for a large portion of the genetic risk for autoimmunity in the population. The HLA alleles that associate with rheumatic diseases are examples of this, as are several of the new associations with RA and other autoimmune disorders such as *PTPN22*.⁹² By common variants, we generally mean variants that are present in the population at frequencies 5% or more, and certainly not less than 1%. However, there is no a priori reason to reject the hypothesis that many rare variants actually account for a significant fraction of the genetic burden of disease. The main reason that common variants have been a focus of research is because the current technologies are particularly well suited to investigate them. This is about to change, with the advent of new technologies that permit resequencing on a massive scale; routine sequencing of entire individual human genomes is probably not more than 5 years away. A seminal finding with respect to the importance of rare variants involves regulation of plasma levels of

lipoproteins,^{93,94} and examples of rare variants contributing to autoimmune diseases are beginning to emerge.⁹⁵⁻⁹⁸ Thus we are still relatively early in the whole genome era of genetic mapping.

Estimating the Size of the Genetic Contribution to Rheumatic Diseases

Epidemiologic studies of familial aggregation and twin concordance for autoimmune diseases are an important background for assessing the genetic contribution to these disorders. The general approach is to compare disease prevalence in groups of individuals with different degrees of genetic relatedness. The most common groups used for such studies are genetically identical individuals (monozygotic [MZ] twins) and individuals who share approximately 50% of their genetic variation in common (dizygotic [DZ] twins and siblings), compared with “unrelated” individuals in the background population. Of course, all humans are related in the sense that we descend from common ancestors, but randomly selected individuals in the population generally differ by little more than 0.1% of their genomes of 3.2 billion base pairs, or 3 to 4 million base pairs.

The use of such family and background population prevalence data to calculate risk ratios remains a primary method of estimating the overall size of the genetic component in complex diseases.⁹⁹ For example, one can estimate the RR of disease for siblings of affected individuals compared with the general population. This leads to a value called λ_s , or RR to sibs, which is calculated as follows:

$$\lambda_s = \frac{\text{Disease prevalence in siblings of affected individuals}}{\text{Disease prevalence in general population}}$$

Obtaining a reliable value of λ_s depends on having accurate estimates of disease prevalence in the two comparison groups. This is not a trivial matter. A firm diagnosis of autoimmune disease is difficult to make in large population surveys, with errors in both directions possible. Underestimation may occur because of the lack of reporting of disease that is no longer active. Overestimation may result from inadequate distinction between different forms of autoimmune disease. Despite these difficulties, a range of values for λ_s has been established for many of the common autoimmune disorders.¹⁰⁰ Table 21-8 lists representative examples. With the exception of ankylosing spondylitis, most autoimmune disorders appear to have a λ_s in the range of 10 to 20.

Table 21-8 Familial Clustering of Selected Autoimmune Diseases, as Measured by the Relative Risk to Siblings (λ_s) and Monozygotic Twins (λ_{MZ})

Disease	λ_s	λ_{MZ}
Type 1 diabetes mellitus	15	60
Rheumatoid arthritis	3-10	20-60
Multiple sclerosis	20	250
Systemic lupus erythematosus	20	250
Ankylosing spondylitis	54	500

From Lander ES, Linton LM, Birren B, et al: Initial sequencing and analysis of the human genome, *Nature* 409:860-921, 2001.

Table 21-8 also shows the estimates for λ_{MZ} . Analogous to the calculation for λ_s , λ_{MZ} is calculated by the following:

$$\lambda_{MZ} = \frac{\text{Disease prevalence in identical (MZ) co-twins of affected individuals}}{\text{Disease prevalence in general population}}$$

The value λ_{MZ} can be interpreted as an estimate of the maximal genetic risk for the disease. This assumes that all the increased risk to an MZ co-twin results from the fact that they share the same genetic polymorphisms. This assumption is clearly not entirely correct because at least some environmental sharing probably contributes to the risk. However, it is notable that the estimated value for λ_{MZ} is quite high for many autoimmune disorders, and this emphasizes the fact that MZ twin concordance rates must be interpreted in light of the background population prevalence of the disease. Thus a relatively low MZ twin concordance rate does not necessarily imply a low genetic component to the disorder. Of course, the absence of complete concordance for disease among MZ twins indicates the need to include environmental, developmental, and stochastic factors in order to fully understand the role of genetics.

Screening the Entire Genome for Disease Genes: Approaches Based on Linkage

There are two basic methods of whole genome analysis, one based on linkage and the other based on association.¹⁰¹ Linkage methods depend on the ability to track polymorphic genetic markers in families and to show that these genetic markers co-segregate with the disease phenotype in families where there are multiple members affected. Thus multiplex families are required for linkage analysis. The details of the statistical methods are complex but are generally based on examining the likelihood of a particular pattern of co-inheritance of marker and disease (linkage), compared with the likelihood that there is no linkage (the null hypothesis). A measure of this likelihood is referred to as the LOD (log of the odds) score, with a LOD score greater than 3 generally interpreted to indicate significant evidence of linkage when markers across the entire genome are examined. Ott¹⁰² described linkage methods in detail in 1999. One advantage of linkage analysis is that the entire genome can be effectively interrogated using less than 500 informative microsatellite markers, or around 5000 SNP markers.⁸⁷

Linkage analysis has been applied with great success to the analysis of rheumatic diseases that exhibit a clear mendelian pattern of inheritance (e.g., dominant or recessive). In 1992, familial Mediterranean fever was mapped to chromosome 16,¹⁰³ and this led to the identification of the gene for this disease in 1997.¹⁰⁴ In addition, an entirely new class of familial periodic fever syndromes has been localized to mutations in the TNF receptor 1 gene on chromosome 12.^{105,106} Thus for highly penetrant mendelian disorders, classical linkage analysis is a powerful means of identifying the underlying molecular basis of disease. However, one of the drawbacks to classical linkage analysis is that, to be most useful, it should be applied to disorders with a high penetrance and a known genetic model (e.g., dominant vs.

recessive). An alternative approach based on linkage, broadly called *allele sharing*, is preferred for the study of autoimmune diseases that have a complex genetic basis.¹⁰¹

The most common approach to allele sharing is the affected sibling pair (ASP) method. This method is based on a simple question: When two sibs are both affected with a disease, do they share alleles at particular genetic markers more frequently than would be expected by chance? Figure 21-8 illustrates this basic approach. In this family two siblings are affected, and the first-born sibling (sib 1) has inherited alleles 1 and 3 at a marker locus, X. By the laws of mendelian inheritance, sibling 2 has a 25% chance of inheriting these same two alleles and has a 25% chance of inheriting neither of these alleles (i.e., sib 2 inherits 2,4 and shares nothing with sib 1 at locus X). By a similar reasoning, there is a 50% chance that these two siblings will share one allele in common. This 25:50:25 distribution of sharing 0, 1, or 2 haplotypes is expected if there is no linkage between the disease and the marker locus. However, if a gene that lies near the marker locus is involved in disease risk, a significant deviation toward increased sharing among affected siblings will be observed. The closer the marker is to the disease locus, the greater the deviation will be from a 25:50:25 distribution. By examining large numbers of affected sibling pairs in this manner, the investigator can develop statistical evidence that this is the case using a standard χ^2 analysis, with the null hypothesis being that there is no increased sharing at the marker locus.

ASP analysis has a number of distinct advantages and disadvantages. Only affected individuals are used, and the problem of falsely assigning a family member as “unaffected” is eliminated. This is a major issue for diseases such as RA because the disease may not express itself until later in life. ASP analysis can be done without committing to a specific model of inheritance (i.e., recessive or dominant). As with linkage in general, the ASP methods suffer from having relatively low power to detect genes that confer only modest risk.¹⁰¹ This means that quite large numbers (hundreds or

thousands) of multiplex families are required to obtain statistically significant results.

Linkage analysis based on allele sharing began to be applied to genetically complex rheumatic and autoimmune diseases in the 1990s and has resulted in a few successes, most notably the identification of the NOD2 gene as a major risk factor for Crohn’s disease.^{107,108} Linkage analysis has provided evidence for numerous risk genes involved in lupus.¹⁰⁹ The presence of a linkage peak (LOD score > 3.5) on chromosome 2q in RA sibling pairs¹¹⁰ led to the identification of STAT4 as a risk gene for RA, as well as lupus.¹¹¹ Thus although challenging to carry out, linkage can occasionally be applied successfully to complex diseases that do not have a clear mendelian pattern of segregation.

Screening the Entire Genome for Disease Genes: Approaches Based on Association

Compared with linkage analysis, association methods have much greater statistical power to detect genetic effects.¹⁰¹ However, in contrast to the relatively modest numbers of markers used for linkage studies, hundreds of thousands or even millions of genetic markers are currently utilized to carry out a comprehensive genome-wide study using association methods. This is the basis of the so-called genome-wide association study, or GWAS. For scanning the whole genome, GWAS has generally replaced linkage methods except in special situations in which large multiplex families suggest the presence of a mendelian pattern of inheritance.

The success of whole genome association studies is critically dependent on taking advantage of the underlying haplotype structure of the genome, which in turn reflects the ubiquitous presence of linkage disequilibrium across the genome, as discussed earlier. Thus as Figure 21-6 shows, for the region around the *PTPN22* gene on chromosome 1, common variation in large segments of most genetic regions can be interrogated using just a few markers that “tag” the common haplotypes. One can think of these patterns of haplotype variation a kind of bar code of common haplotype across a genomic region, as shown in the central region of Figure 21-6 and described in Table 21-7. As mentioned, the International HapMap Project has established online resources (www.hapmap.org) that allow users to easily explore the haplotype structure of any region of the genome.¹¹² The HapMap website also contains informative tutorials on genetic diversity and the use of this resource.

In 2005, the complement regulatory protein Factor H was identified as a significant risk factor for age-related macular degeneration,^{113,114} and this report essentially kicked off the GWAS era. Shortly after, a second major GWAS study led to the identification of the IL-23 receptor as a risk gene for Crohn’s disease.¹¹⁵ In the intervening 5 years, GWAS studies have proven to be particularly fruitful when applied to autoimmune disorders. In the aggregate, there are now nearly 200 distinct chromosomal regions that have been identified as containing risk loci for major autoimmune diseases including type 1 diabetes,¹¹⁶ RA,¹¹⁷ systemic lupus,¹¹⁸ and inflammatory bowel disease.¹¹⁹ As large datasets are assembled for some of the rarer or less studied autoimmune disorders,^{120,121} GWAS will continue to play a role in genetic analysis.

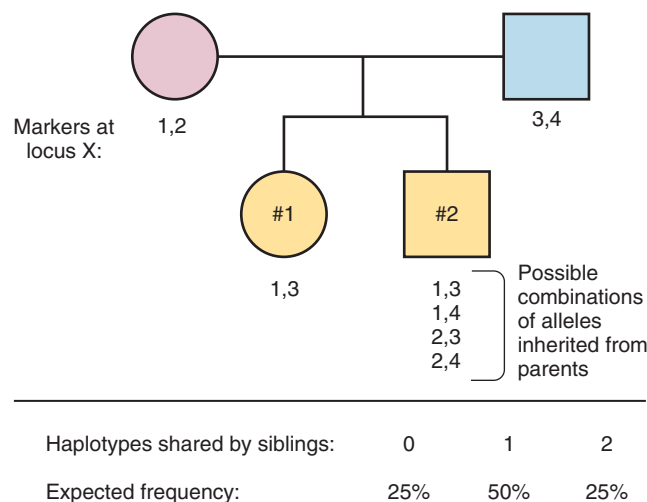

Figure 21-8 A nuclear family with two affected children (affected sibling pair). The possible distribution of alleles at an autosomal locus, X, is shown for sib 2, along with the predicted frequency of shared haplotypes among the sibs. In these families researchers can detect linkage using affected sibling pair analysis (see text).

Overlapping Susceptibility Genes and Pathways for Autoimmune Diseases: Getting to Function

Obviously, from the previous discussion, the genetic factors underlying autoimmunity are quite complex and the full picture is still emerging. Nevertheless, some themes are evident from the current data. First, many of the newly discovered risk genes appear to be involved in multiple different autoimmune disorders. In contrast to HLA, this often seems to involve the same alleles conferring susceptibility across many diseases, as exemplified by *PTPN22* (see later). Secondly, many of the risk loci fall into functional categories that suggest common underlying mechanisms. Of course, the assignment of a gene to a particular functional category is subject to bias, and the same gene can be found in multiple categories. Nevertheless, many genes involved in lymphocyte signaling, cytokine pathways, innate immune pathways, and interferon pathways are found associated with autoimmunity. These have been discussed in several recent reviews,^{122,123} and a full discussion of these data is beyond the scope of this chapter. However, several examples that highlight these trends are provided as follows.

In 2004, an association between the intracellular phosphatase, *PTPN22*, was reported for a number of autoimmune diseases including type 1 diabetes,¹²⁴ RA,¹²⁵ systemic lupus,¹²⁶ and autoimmune thyroid disease.¹²⁷ With ORs consistently in the range of 1.5 to 2, this was the first compelling demonstration that a specific common allelic variant outside of HLA can confer risk for multiple different autoimmune phenotypes and has been consistently replicated.⁹² In this case, a nonsynonymous change in one of several SH3 binding sites in *PTPN22* (a tryptophan substitution for arginine at codon 620) was shown to disrupt the normal association of *PTPN22* with a Csk, an intracellular tyrosine kinase.^{124,125} Knockout of *PTPN22* in rodents leads to dramatic overactivity of T cells, but the exact functional consequence of the human risk allele remains controversial. However, there is little doubt that *PTPN22* is involved in setting thresholds for T cell receptor signaling through Lck,^{128,129} as well as B cell receptor signaling.¹³⁰ *PTPN22* is also found in many other hematopoietic cells, and its function in these cells is largely unknown. Interestingly, all of the autoimmune diseases associated with *PTPN22* have a prominent autoantibody component, and thus a specific role in regulating humoral immunity appears to be a unifying feature. Notably, the *PTPN22* risk allele is actually protective for Crohn's disease and has no role in risk for multiple sclerosis, emphasizing the likely presence of distinct mechanisms of pathogenesis in these disorders. Thus *PTPN22* is a prime example of how the discovery of new disease associations with relatively modest effect can redirect hypothesis-driven research into new pathways.

In 2005 researchers showed that interferon regulatory factor 5 (IRF5) was associated with susceptibility to systemic lupus,¹³¹ and they replicated it shortly thereafter.¹³² This was a satisfying observation because activation of interferon pathways is clearly central to the pathogenesis of lupus and related disorders.^{133,134} Since these original observations, it is now apparent that multiple genes in interferon pathways are involved in lupus susceptibility.^{118,135} Interferon has emerged as a potential drug target,¹³⁶ and there is renewed appreciation and interest in the role of interferon

regulation in the immune response generally.¹³⁷ The involvement of multiple genes in interferon pathways as risk factors for autoimmune diseases provides important support for continuing biologic studies in this field, as well as the potential for new insights into the details of how this pathway is regulated.

The theme of common variants in genes that share susceptibility alleles across different diseases with common underlying mechanisms begs the question of how these genetic variants affect the normal immune response. Do these genetic variants confer survival advantages? Could one examine the “normal” range of immune response phenotypes to detect a state of risk, without actually defining the complex underlying genetics? The entire issue of what is the normal range of immune function has come under renewed interest¹³⁸ and has driven interesting studies of function of autoimmune risk loci in subjects without disease.¹³⁹ Indeed, the study of the normal immune system may be the key to understanding how complex arrays of risk alleles actually lead to disease in an individual.¹⁴⁰ Thus in addition to further expansion of gene discovery efforts, advances in the genetics of autoimmunity are going to require more sophisticated ways of phenotyping the normal immune system, as well as the diseases themselves.

FUTURE CHALLENGES OF GENETICS IN RHEUMATIC DISEASES

This chapter has discussed fundamental concepts and analytic approaches that are central to modern human genetics. Although the underlying concepts will not change, it is obvious that genetic technologies are rapidly advancing, with routine analysis of the full sequence of entire human genomes only a few years away. We are already in an era where the available genetic data are exceeding our capacity to analyze them. Therefore the future challenges are likely to be focused mainly on extracting the meaning of genetic data in a way that is useful, on many levels. We need to connect genetic variation to phenotypic variation from the most basic levels of biologic action to systems regulation and finally to disease pathogenesis and heterogeneity. As emphasized in the last section, this implies a major emphasis on more precise phenotypic measurements both in vitro and in vivo including assessment of population diversity. This is going to be an iterative and integrative process; it is only in the setting of relevant (and measurable) phenotypic diversity that the significance of genetic variation can be understood.

Aside from the basic problem of functionally connecting genotype to phenotype, several areas are poised for expansion. One of these is epigenetics. This concerns the varied mechanisms by which the genome can be chemically altered to affect gene function, and this will surely require a separate chapter by the next edition of this textbook. These alterations can be induced by parental effects, developmental events, and environmental influences, and working out the details of these interactions is sure to bring surprises and provide us with a new appreciation for the complexity of gene-environment interactions. Finally, the complexity of the genetic factors involved in rheumatic diseases makes it unlikely that there will be a rapid translation of genetic information into practical action at the level of patient care

in the near future. Useful algorithms will almost certainly require combining genetic information with other biomarkers, both for diagnosis and risk assessment, as well as treatment decisions. Here again, genotypic and phenotypic information need to be joined to achieve long-term goals.

KEY POINTS

Epigenetic changes have a lasting effect on gene expression by modification of histone tails and DNA.

DNA methylation silences gene expression, while histone modifications can enhance or suppress gene transcription.

MicroRNAs are small noncoding RNA molecules that target mRNA molecules in a sequence-specific way and inhibit their translation.

The epigenome is strongly influenced by environmental changes; this might be the missing link between environmental risk factors and disease development in many diseases.

In immune and stromal cells in rheumatic diseases, DNA is often globally hypomethylated, but hypermethylated promoters can be found as well at specific loci.

Increased basal levels of specific microRNAs in rheumatoid arthritis could be shown to be due to DNA hypomethylation.

The stably activated phenotype seen in rheumatoid arthritis fibroblast-like synoviocytes can be explained in part by changes in the epigenome.

The term *epigenetic* describes a number of chromatin modifications that stably alter gene expression without changing the sequence of the DNA. In this way, epigenetic mechanisms shape the phenotype of a cell without changing the genotype. In the last few years, the study of epigenetic mechanisms strongly progressed, yielding insight into the mechanisms by which epigenetic chromatin modifications regulate gene expression. It became clear that epigenetic mechanisms are important in cellular development and differentiation, as well as in adaptation to changes in the environment. In particular, Conrad Waddington is given credit for advancing the hypothesis that the environment plays a sculpting role in development and cell fate via epigenetic mechanisms.¹ Epigenetics supports the idea that changes in gene expression that stem from long-term exposure to a certain signal get imprinted, become independent of the activating stimulus, and persist even in its absence. Accordingly, the impact of nutrition, toxins, or infection on gene expression is maintained, leading to fixed changes in the phenotype. This change helps the cell to adapt but might also promote pathologic cellular behavior.

With the acquisition of new knowledge, the original definition of *epigenetic processes* as heritable changes in DNA without alterations in the sequence became a matter of debate. Particularly divisive is the matter of heritability. Even though the classic definition demands that epigenetic

Epigenetics

CAROLINE OSPELT • STEFFEN GAY

modifications persist through mitosis and meiosis (i.e., are inherited to the next generation), transient modifications that indirectly initiate stable changes more and more are put together under the term *epigenetics*. Giving credit to this view, Bird described epigenetic events as “the structural adaption of chromosomal regions so as to register, signal, or perpetuate altered activity states.”² In addition to the well-established epigenetic role of DNA methylation, this definition includes a variety of more transient histone modifications such as acetylation, methylation, or phosphorylation that underlie epigenetic effects, and that will be discussed in this chapter along with the influence of SUMOylation, ubiquitination, adenosine diphosphate (ADP) ribosylation, and microRNA.

EPIGENETIC MECHANISMS

DNA Methylation

DNA methylation is the classic and probably best studied epigenetic modification. Thereby, methyl marks are added to the cytosine ring of cytosine-phosphatidyl-guanine (CpG) dinucleotides. In addition, recently also non-CpG, but CHG or CHH, where H stands for A, C, or T, DNA methylation has been found to occur.³ This type of DNA methylation seems to be important mainly in pluripotent stem cells and disappears during differentiation. CpG methylation of DNA preferably is found at sites with a high percentage of CpGs, so-called CpG islands. Recently however, differences in the methylation pattern between tissues were found to occur frequently not at CpG islands, but at regions with lower CpG density that lie around 2 kb upstream or downstream of CpG islands, so-called CpG island shores.⁴ At both locations, DNA methylation leads to transcriptional repression.

During embryonic development, de novo methylation marks are established by DNA methyltransferase (DNMT) 3a and 3b. During somatic cell replication, methylation marks are stable and are maintained by DNMT1. Gene silencing by DNA methylation is crucial for the formation of heterochromatin. It promotes stable silencing of repetitive sequences such as alu sequences and retrotransposons, genomic imprinting, X chromosome inactivation in female mammals, and tissue-specific gene expression. However, in recent years it has become clear that DNA methylation is more dynamic than was previously assumed. Global genomic demethylation is seen in the paternal pronucleus shortly after fertilization, and gene-specific demethylation has been observed.⁵ Promoters of estrogen-responsive genes, for instance, are periodically methylated and demethylated depending on ligand binding of the estrogen receptor α .^{6,7}

Figure 22-1 DNA methylation. Generally, DNA gets methylated at the pyrimidine ring of the cytosine. The methyl mark leads to changes in the chromatin structure and recruits effector molecules. A, adenine; C, cytosine; G, guanine; T, thymine.

Methylation marks are believed to be removed passively (e.g., DNMT1 does not restore methyl marks after replication) or actively. Different mechanisms have been proposed to account for active DNA demethylation; however, as yet definite experimental proof in mammalian cells exists for none of them.⁸ In short, conceivable mechanisms for active DNA demethylation include enzymatic removal of the methyl group, excision and substitution of 5-meC by C, oxidative demethylation thereby converting 5-meC to 5-hydroxymethylcytosine, and demethylation by S-adenosylmethionine (SAM) domains, forming a 5-meC radical.

DNA methylation can directly interfere with binding sites of transcription factors, thereby inhibiting induction of gene expression, or transcriptional repressors can bind to methylated DNA, blocking transcription. By their presence, they inhibit the binding of transcription factors and recruit histone deacetylases, which change the histone code and further block gene expression (Figure 22-1).

Histone Modifications

Within the nucleus, DNA is packaged around an octamer comprising homodimers of four different histone proteins: H2A, H2B, H3, and H4. This so-called nucleosome is stabilized and kept in place by H1. Each histone protein has an N-terminal tail, which is the main target of a variety of histone modifications. Amino acids in the histone tails can be acetylated, methylated, phosphorylated, ubiquitinated, SUMOylated, ADP ribosylated, and deiminated (Figure 22-2). Not all of these modifications are equally well studied, and detailed knowledge about their regulation and interactions is still missing. The sum of the different histone modifications at a distinct region of the genome is called the *histone code*. It is generally believed that the histone code can influence transcriptional activity directly by affecting chromatin structure, thereby making it more or less accessible for transcription factors and indirectly leading to the attraction of effector molecules that in turn recruit and stabilize the transcription machinery.⁹ For most histone modifications, it is yet impossible to predict whether they enhance or restrict transcriptional activity and how this will influence the biologic output. Also, more and more accumulating evidence indicates that the different histone modifications are strongly interconnected and can enforce or counteract each other. Nevertheless, some modifications can clearly be associated with transcriptionally active or inactive chromatin (Table 22-1).

Acetylation

Histone acetylation generally is associated with transcriptional activation. It is believed that histone acetylation directly opens the chromatin structure, allowing easier access to the transcription machinery.¹⁰ Acetylation loosens the interaction of the negatively charged DNA with the positively charged lysine by neutralizing the charge of lysine.¹¹ In addition, acetylated histone tails are bound by bromodomain effectors.¹² Members of the bromodomain family support protein-protein interactions to assemble a multicomponent complex involved in transcriptional activation. Histone acetylation is catalyzed by histone acetyltransferases (HATs) and is counteracted by histone deacetylases (HDACs). Up to now, two main groups of HATs—type A and type B—have been described, whereby the nuclear type A HATs are those believed to influence transcriptional activity.¹³ The family of HDACs comprises four classes. Classes I, II, and IV consist of 11 HDACs—HDAC1 to HDAC11—that are zinc dependent;

Figure 22-2 Histone modifications. The different histones get modified at specific amino acids in their tails. These modifications can change the chromatin structure or can lead to the binding of effector molecules. K, lysine; R, arginine; S, serine; T, threonine. Modifications: Ac, acetylation; Cit, citrullination; Me, methylation; P, phosphorylation; SUMO, SUMOylation; Ub, ubiquitination.

Table 22-1 Epigenetic Modifications

Modification	Location	Effect	Mechanism	Enzymes
DNA				
Methylation	Cytosine	Repression	Blocking of transcription factor binding Recruitment of effectors	+DNMT3a/b (de novo), DNMT1 (maintenance)
Histones				
Methylation	Lysine, arginine	Activation/repression	Chromatin structure Recruitment of effectors	+HMT –HDM
Acetylation	Lysine	Activation	Chromatin structure Recruitment of effectors	+HAT –HDAC
Deimination	Methylated arginine	Repression	Chromatin structure	+PAD4
Phosphorylation	Serine, threonine	Activation	Recruitment of effectors	+Kinases –Phosphatases
Ubiquitination	Lysine	Activation/repression	Recruitment of effectors	+E3 ubiquitin ligases, E2 ubiquitin-conjugating enzymes
SUMOylation	Lysine	Repression	Recruitment of effectors	+E1 SUMO-activating enzymes, E2 SUMO-conjugating enzymes, E3 SUMO ligases–isopeptidases
ADP ribosylation	Glutamic acid	Activation	?	+PARP, MART

DNMT, DNA methyltransferase; HAT, histone acetyltransferase; HDAC, histone deacetylase; HDM, histone demethylases; MART, mono-ADP-ribosyltransferases; PAD4, peptidyl arginine deiminase type 4; PARP, poly-adenosine diphosphate (ADP)-ribosyltransferases; SUMO, small ubiquitin-related modifier.

class III includes the nicotinamide adenine dinucleotide (NAD)-dependent sirtuins, SIRT1 to SIRT7. HDACs and HATs not only modify histones, they also form complexes with transcription factors, oncoproteins, and tumor suppressors and regulate their activity by changing the acetylation status.¹⁴

Methylation

Histone methylation marks are highly complex because histones can be monomethylated, dimethylated, or trimethylated; in addition to lysine, arginine residues can be modified. Depending on the methylated site, histone methylation leads to transcriptional activation or repression. A prominent example of this divergent effect is trimethylation of histone 3 at the fourth lysine (H3K4me3), which is associated with active genes, in contrast to H3K27me3, which is found at silenced genes.^{15,16} It is interesting to note that the location of the methyl mark in relation to the regulated gene plays a role. Thus H3K9 methylation at the promoter region silences transcription, but within the coding region, H3K9 methylation was found to be associated with actively transcribed genes.¹⁷ Similar to histone acetylation, methylation of histone tails changes chromatin configuration and binds effector proteins. Methyl marks are recognized by plant homeodomain (PHD) fingers and the Royal-superfamily of chromatin-binding proteins, including chromodomain, tudor, and MBT domains.⁹ Histone methylation is catalyzed by histone methyl transferases (HMTs). The various members of this group of enzymes are highly specialized in methylating selected lysines or arginines to a certain degree (monomethylation, dimethylation, trimethylation).¹³ Lysine demethylases that counteract the action of HMTs on methylated lysines may contain an amine oxidase or a Jumoni C (JmjC) domain. Up to now, no arginine demethylase has been found that can reverse methylated arginine to arginine. Peptidylarginine deiminase 4 (PAD4) converts methylated arginine to citrulline, and this

leads to transcriptional repression.¹⁸ Because in this step also the imine group of the arginine is removed, this reaction is termed *deimination*.

Phosphorylation

Histone phosphorylation is a fast way to induce gene expression, particularly after activation of mitogen-activated protein kinase (MAPK) pathways.¹⁹ Even though histone phosphorylation itself seems to be rather transient, reports suggest that histone phosphorylation influences other histone modifications such as acetylation and methylation, thereby indirectly inducing prolonged changes in the histone code.^{20,21} Phosphorylation of histones occurs at serine and threonine residues and is mediated by kinases and removed by phosphatases.²² Similar to acetylation, phosphorylation opens the chromatin structure by adding a negative charge to the histone but also leads to the attraction of effector proteins. The best studied effector proteins binding phosphorylated histones are 14-3-3 proteins and BRCA1 C-terminus (BRCT) domains.⁹

SUMOylation

E1 SUMO-activating enzymes, E2 SUMO-conjugating enzymes, and E3 SUMO ligases are the enzymes that add small ubiquitin-related modifiers (SUMOs) to histone lysines.²³ SUMOylation can be reversed by isopeptidases. Even though details about gene regulation after histone SUMOylation are still unclear, it is known that SUMOylation mostly represses gene expression in close cooperation with other histone modifications.²⁴ As a counterregulatory mechanism, SUMO marks are increased after histone acetylation and recruit HDACs to remove acetylation.²⁴ Furthermore, SUMOylated histones associate with heterochromatin protein (HP)-1, a methyl-lysine binding protein that interacts with HMTs to repress transcription.²⁵

Ubiquitination

Ubiquitin ligases and proteases control histone ubiquitination and deubiquitination, respectively. Ubiquitination of histone 2A and 2B generally activates gene transcription. However, other reports show that histone ubiquitination can repress transcriptional activity.²⁶ Similar to SUMOylation, ubiquitination is strongly connected to other histone modifications and mainly alters gene expression via recruitment of effector molecules, which subsequently results in histone methylation.²⁷

ADP Ribosylation

Histones can be mono-ADP ribosylated by mono-ADP-ribosyltransferases (MARTs) or poly-ADP ribosylated by poly-ADP-ribosyltransferases (PARPs).²⁸ Little is known about this histone modification, and neither site specificity nor function has been clearly defined. However, synergy between histone acetylation and ADP-ribosylation has been described.²⁹

Epigenetics and Noncoding RNAs

Noncoding RNAs (ncRNAs) are transcribed RNA molecules that do not translate into protein. Long known ncRNAs include transfer RNA (tRNA) and ribosomal RNA (rRNA). More interesting with regard to epigenetic modifications, however, are the more recently discovered long ncRNAs such as the *Xist* (X inactive specific transcript) transcript and small ncRNAs such as microRNAs (miRs). In female cells, *Xist* is transcribed from the later inactivated X chromosome (Xi). It specifically binds to Xi and promotes its silencing by histone ubiquitination, methylation, and loss of acetylation.³⁰ Recently, another long ncRNA named *Air* has been shown to interact with a specific set of genes and to recruit the chromatin-modifying machinery to these loci.³¹ In plants and yeast, multiple examples of interaction between ncRNAs and epigenetic chromatin modifications have been found.³²⁻³⁴ Overall these data suggest that recognition of complementary DNA sequences by ncRNAs might guide epigenetic modifications to specific genomic loci.

MicroRNAs are small ncRNAs that are encoded in intergenic regions and overlapping introns or exons of other genes.³⁵ The primary miR transcript (pri-miR) containing the information of a single miR or an miR cluster is further processed by an enzymatic complex that includes the RNase III enzyme Droscha. After formation of a hairpin, the precursor miR (pre-miR) is exported to the cytoplasm (Figure 22-3). Pre-miRs are further cleaved by the RNase III enzyme Dicer and are released as short duplexes, on average 22 oligonucleotides long, which constitute the mature miR. From this duplex, two mature miRs can be formed. However, dependent on the thermodynamic stability of each end, in some cases one of the strands is fast degraded; this is usually called the miR star (*) or passenger strand.³⁶ The other strand, termed the *guide strand*, is more stable and biologically active. In other cases, both strands are equally stable, and the miR from the 5' end is referred to as 5p, whereas the miR from the 3' end is denominated 3p. After incorporation into the RISC (RNA-induced silencing complex),

mature miRs bind to the 3' untranslated region of their target mRNA and modulate their expression by degradation or by inhibition of protein translation. The system is highly promiscuous, so that one miR can modulate expression of multiple proteins, and expression of one protein is influenced by a variety of different miRs. Mainly the miR sequence from base 2 to base 8 or 9 from the 5' end, the so-called seed region, plays a crucial role in target recognition.³⁷ In addition, the position of the complementary sequence on the gene and the presence of other miR target sites influence the repressive action of miRs.³⁸ The expression of around 30% of all genes is believed to be regulated via miRs.³⁹

Recently more and more connections between miRs and epigenetics have been found. It is estimated that 50% of the genes coding for miRs are directly controlled by DNA methylation.⁴⁰ A comparison between methylation patterns of various tissue types revealed that a large proportion of differentially methylated regions are located outside promoters regions in conserved intergenic elements, where miRs are coded.⁴¹ In cancer, these regions are often found to be affected by genomic changes such as deletions, translocations, and amplifications, leading to disturbances in the miR expression pattern.⁴²

As epigenetic mechanisms influence the expression of miRs, miRs regulate the expression of important components of the epigenetic machinery. By targeting chromatin-modifying enzymes, miRs subtly change the epigenome, thereby regulating gene expression. Several miRs have been shown to target DNMT1, thereby promoting loss of DNA methylation.⁴³ Also, HDACs are targets of miRs, making them potential modulators of histone acetylation.^{44,45}

EPIGENETICS IN DISEASE

In the study of complex diseases, one of the main tasks is to unravel genetic and environmental influences in the search for causative factors and prediction parameters. Twin studies comparing concordance rates of diseases in monozygotic twins can give insight into genetic and environmental influences of a disease. For example, a predominance of genetics is suggested in celiac disease, in which concordance rates between monozygotic twins are greater than 80%.^{46,47} In rheumatoid arthritis, however, heritability accounts for only maximal 60% of disease prevalence, suggesting a strong impact of nongenetic factors on disease development.⁴⁸ Changes in epigenetics might explain this “missing heritability.” In particular, the impact of environmental factors on epigenetics has raised considerable attention in the last few years. Differences in the epigenome have been detected in monozygotic twins. They accumulate over time and might be one of the reasons why one twin develops a certain disease while the other stays healthy.⁴⁹ It has been proposed that the epigenomes of monozygotic twins diverge more and more because of nonshared environmental influences. Also, the fidelity of the enzymes maintaining epigenetic modifications during mitosis is much lower compared with the DNA polymerases, leading to small changes in epigenetic modifications after each cell cycle.⁵⁰

Alterations in the epigenetic code have been found in a variety of pathologic conditions, ranging from cancer⁵¹ to autoimmune and chronic inflammatory diseases⁵² to

Figure 22-3 MicroRNA biogenesis. MicroRNAs are coded in exonic, intronic, or intergenic regions of the genome. They are transcribed by RNA polymerase II individually or in clusters. Drosha and Dicer are RNase III enzymes that further process the primary transcript (pri-miR) and the precursor miR (pre-miR), respectively. The resulting miR-Duplex is loaded onto the RNA-induced silencing complex (RISC), where the separated strands bind their target mRNA and induce its degradation or inhibit its translation.

psychiatric conditions.⁵³ However, it is not clear how far these changes are causative of disease, or whether they are bystander effects. In some cases, defects in the epigenetic code have been found to directly cause disease.⁵⁴ Particularly, specific imprinting control regions have been found to be sensitive to changes in DNA methylation.⁵⁵ About 80 genes in the human genome are currently known to be regulated via genomic imprinting. In these genes, epigenetic silencing of the maternal or paternal allele is of importance for balanced gene expression. Naturally caused by the haploid expression of genomically imprinted genes, the consequences of aberrant imprinting include loss of function, whereas loss of imprinting leads to highly increased levels of the gene product, both of which induce developmental disturbances and disease. For example, Beckwith-Wiedemann syndrome, which is characterized by macrosomia, increased tumor risk, and facial dysmorphism, can be caused by loss of maternal allele-specific DNA methylation at one specific imprinting control region, resulting in increased expression of genomic imprinted genes, or by hypermethylation of the maternal allele at another region, leading to loss of expression.^{56,57} Other examples of diseases associated with dysregulated genomic imprinting are Angelman syndrome and Prader-Willi syndrome.

Most studies elucidating the role of epigenetic changes in disease have focused on cancer.⁵⁸ Genome-wide hypomethylation is the most commonly found epigenetic alteration in many tumor types, but changes in histone acetylation

and methylation have been demonstrated.⁵⁹⁻⁶¹ DNA hypomethylation can lead to activation of retrotransposons such as endogenous retroviruses, long interspersed nucleotide elements (LINE)-1, and alu repeats. These changes induce chromosome instability and influence the transcriptional activity of nearby genes.⁶² In addition, promoter-specific hypomethylation or hypermethylation, altering the expression of tumor suppressor genes and oncogenes, gives tumor cells a growth advantage.

EPIGENETICS AND RHEUMATIC DISEASES

The study of epigenetic changes in rheumatic diseases is only at its beginnings but nevertheless has already provided interesting insight into the pathogenesis of these diseases. In particular, dysregulation of the immune response and lack of inflammatory resolution are thought to be associated with epigenetic changes in specific cell types.

Systemic Lupus Erythematosus

The importance of epigenetic changes in systemic lupus erythematosus (SLE) has been underlined by the finding that monozygotic twins discordant for SLE show significant differences in DNA methylation patterns.⁶³ Accordingly, T cells from SLE patients were found to be globally hypomethylated as the result of reduced levels of DNMT1.⁶⁴

Overexpression of miR-21 and miR-148a, both of which directly and indirectly lead to repression of DNMT1, contributes to the loss of methyl marks in lupus T cells.⁶⁵ Also, a defect in signaling through the ras-MAPK pathway found in T cells from patients with SLE results in low levels of DNMT1, thereby supporting global DNA hypomethylation.⁶⁶ A direct connection between autoreactivity and loss of DNA methylation in T cells is supposed because DNA demethylation of normal T cells by 5-azacytidine promotes loss of tolerance, and in vitro hypomethylated T cells induce a lupus-like disease when transferred to mice.⁶⁷ Furthermore, hypomethylated T cells increase macrophage cell death, which, in conjunction with reduced clearing of resulting cell debris, is proposed to lead to the induction of anti-DNA antibodies. This phenomenon could be based on increased expression of perforin through hypomethylation of its promoter in lupus T cells, which promotes killing of monocytes and macrophages.⁶⁸ For the autoreactivity of lupus T cells in particular, increased levels of CD70 and CD11b could be responsible.^{69,70} Whereas CD70 is thought to be involved in B cell activation, CD11b is important in promoting cell-cell contact between T cells and other cells of the immune system. CD70 and CD11b promoter regions were found to be hypomethylated, as well as hyperacetylated in lupus T cells.⁷¹

As mentioned earlier, DNA methylation is crucial for silencing of repetitive sequences in the human genome. In particular, aberrant expression of human endogenous retrovirus (HERV) sequences has long been implicated in the development of autoimmune diseases.⁷² HERV-E clone 4-1 transcripts were found to be expressed only in peripheral blood mononuclear cells (PBMCs) from SLE patients, but in PBMCs, not from healthy controls.⁷³ Because in vitro demethylation of DNA by 5-azacytidine induced HERV expression, it can be assumed that global DNA hypomethylation could be responsible for aberrant expression of this retrotransposon. Its presence might also lead to the production of autoantibodies, because expression of HERV-E clone

4-1 *gag* transcripts correlates with the presence of the anti-nuclear antibodies anti-U1 ribonucleoprotein (RNP) and anti-Sm.⁷⁴

Even though at certain promoter regions, histones in SLE have been found to be hyperacetylated (e.g., CD70, CD11b), global H3 and H4 acetylation measurements showed decreased histone acetylation in T cells of SLE patients.⁷⁵ Also decreased levels in H4K9 methylation and changes in the H3K4me3 pattern are found in PBMCs of SLE patients and are connected to increased expression of disease-relevant genes.⁷⁶

Rheumatoid Arthritis

The imprinted activated phenotype seen in fibroblast-like synoviocytes (FLSs) in rheumatoid arthritis (RA), characterized by high basal expression of matrix-degrading enzymes, proinflammatory cytokines, and chemokines, is assumed to be maintained by epigenetic changes (Figure 22-4).⁷⁷ Genomic DNA is globally hypomethylated in RA FLSs as the result of low levels of DNMT1, which lead to lack of restoration of methyl marks after cell division.⁷⁸ A further indication for a hypomethylated state is expression of the LINE-1 retrotransposon in FLSs of RA patients.⁷⁹ Reactivation of this retrotransposon in RA induces changes in gene expression (e.g., p38 δ , galectin-3-binding protein, *met* proto-oncogene), possibly contributing to the activated phenotype of FLSs in RA. Specific promoter regions also seem to be hypermethylated in RA FLSs, indicating a generally disturbed methylation pattern, as is also seen in cancer cells. The promoter of death domain receptor 3 (DR-3) is hypermethylated in RA FLSs; accordingly, RA FLSs have decreased levels of DR-3, which might contribute to their well-known resistance to apoptosis.⁸⁰ Global and promoter-specific hypomethylation was also found in T cells of RA patients.⁶⁴ In particular, analysis of the “senescent” CD4⁺-CD28 subset of T cells, which are increased in patients with chronic inflammatory diseases such as RA, revealed that

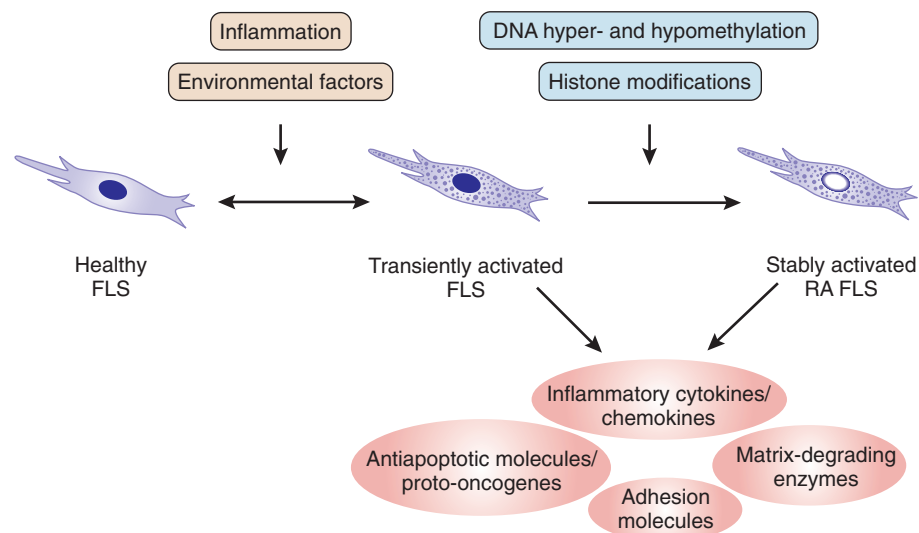

Figure 22-4 Influence of epigenetic mechanisms on the activated phenotype of fibroblast-like synoviocytes (FLS) in rheumatoid arthritis (RA). Joint inflammation and other environmental factors stimulate FLSs to produce a variety of effector molecules. Normally, this activation is reversible and the inflammation is resolved. Epigenetic changes, however, imprint the activated phenotype of FLSs in RA, making them independent of an activating stimulus.

demethylation leads to the specific gene expression pattern seen in these cells. Because of replicative stress, these T cells downregulate ERK and JNK signaling pathways; this is associated with loss of methylation via downregulation of DNMT1 and DNMT3a.⁸¹ Also, DNA methylation of interleukin (IL)-6 and ephrinB1 promoters is decreased in RA lymphocytes, leading to increased expression of these genes in RA patients.^{82,83} In FLSs DNA demethylation with 5-azacytidine induced expression of miR-203.⁸⁴ Basal levels of miR-203 are increased in RA FLSs and strongly correlate with basal expression of IL-6. Also, miR-155 and miR-146a are highly expressed in RA synovial tissues, FLSs synovial fluid, and PBMCs, whereas expression of miR-124a is decreased in RA FLSs.⁸⁵⁻⁸⁹ Because miRs are known to be commonly controlled by DNA methylation, it is feasible to assume that some of the observed changes in miR expression stem from the altered DNA methylation pattern in RA.⁴⁰ However, experimental proof is still missing.

Also histone acetylation seems to be affected in RA. Increased and decreased activity and expression of HDACs have been described in RA synovial tissues.^{90,91} In particular, because TNF stimulation could increase levels of HDAC1 and HDAC2 in FLSs, levels of HDACs could be influenced significantly by anti-TNF treatment. However, it is not clear yet whether differences in lifestyle or medical treatment account for differences in HDAC activity in the analyzed patient groups. Nevertheless, in arthritis animal models, HDAC inhibitors show a strong anti-inflammatory effect.⁹²⁻⁹⁵

An interesting cooperation between different histone modifications has been shown for the regulation of matrix metalloproteinase (MMP)-1 expression in RA. HERV-E clone 4-1 transcripts were found to be expressed only in peripheral blood mononuclear cells (PBMCs) from SLE patients, but not in PBMCs from healthy controls.^{96,97}

Future Directions

The field of epigenetics is rapidly evolving, and immense progress has been made in the analysis of epigenetic mechanisms in health and disease. Some of the main tasks to be addressed in the future are decryption of the histone code and elucidation of mechanisms that guide chromatin modifications to specific genes. For the pathogenesis of any given disease, the question remains which epigenetic changes are the causes, and which are the consequences, of a pathologic state. Irrespective of the answer, the therapeutic control of specific epigenetic changes will more and more attract focus. Up to now, HDAC inhibitors and drugs inhibiting DNA methylation are already in use to treat patients with blood cancer.⁹⁸ However, mechanisms of action of these drugs are not clearly understood. HDAC inhibitors, even though they increase acetylation of histones and accordingly activate gene transcription, also silence the expression of certain genes, probably as the result of modification of nonhistone targets.⁹⁹ HDAC inhibitors and DNA methylation inhibitors are currently in clinical trials for the treatment of a variety of cancers, but could be effective in metabolic, inflammatory, and neurodegenerative diseases. The future will certainly bring new approaches for epigenetic targets such as the modification of specific

histone methyl groups. Also, microRNAs have been targeted successfully in primates to treat hepatitis C.¹⁰⁰ The use of so-called antagomirs will certainly become a novel option for the treatment of rheumatic diseases in the future.

KEY POINTS

The complement system is activated in the joints in rheumatoid arthritis and in vessel walls in vasculitis.

Autoantibodies may activate the complement system, which then contributes to damage at the site of autoantigen expression.

The complement system plays a key role in handling immune complexes, especially those that arise in the circulation. Complement activation is an efficient means to coat antigens so that they adhere to peripheral blood cells and are then phagocytosed or carried to the spleen and liver for disposal. In these organs, the immune complexes are transferred to tissue macrophages for destruction or an immune response.

Complement measurements are helpful in diagnosing and following patients with systemic lupus erythematosus. Low C4 and C3 in the presence of anti-double-stranded antibodies have nearly a 100% specificity for lupus.

In rheumatic diseases featuring complement activation, we lack sensitive day-to-day markers to monitor disease activity. Therefore the amount of complement inhibition required to modulate disease is not known. We also lack knowledge whether C3a/C5a, C4b/C3b, or the membrane attack complex is the key mediator of pathology, as well as which pathway and at which step to block.

Urate crystals and other types of cellular debris activate innate immunity including the complement system.

In this chapter we review the workings of the complement system, with a focus on how the system functions in rheumatic diseases. The involvement of the complement system has long been recognized in two of the most common inflammatory diseases treated by rheumatologists: systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA). What has been learned about the complement system's role in these two diseases likely applies to related syndromes. The goal of this chapter is to help the rheumatologist appreciate the biologic and pathologic relevance of the complement system in rheumatic diseases. This information can also assist in the interpretation of laboratory tests of complement proteins and in the determination of the significance of complement fragments in pathologic specimens.

HISTORICAL ASPECTS

Today, *complement* is a collective term designating a group of plasma and membrane proteins that play a key role in innate and adaptive immunity. The complement system is ancient, predating chordates such as the lamprey and hagfish.^{1,2} Complement was discovered in the late

Complement System

JOHN P. ATKINSON

nineteenth century by experimental pathologists attempting to understand the protective basis of vaccination and the cause of transfusion reactions.³ In these studies, it became apparent that the cell-free portion of blood contained a lytic substance for bacteria and for transfused red blood cells (RBCs). This “factor” was heat labile (destroyed by heating at 56° C for 30 minutes), unstable (it lost activity if serum was left on the bench top overnight), and innate or nonspecific (all individuals had this lytic substance). It was contrasted to antibody, which was heat stable, and only animals immunized to the specific bacteria contained this factor. Through mixing experiments, these two factors were found to be required for lysis—a specific recognition piece (antibody) and a nonspecific lytic piece (complement). In retrospect, this was the discovery of the classical complement pathway and led to its characterization as a heat-labile, bactericidal factor that “complemented” the acquired factor raised by immunization. Similarly, in the blood of patients who recovered from transfusion reactions, a heat-stable substance (antibody) was found that recognized the transfused erythrocytes. However, it did not lyse the transfused cells; rather, it cooperated with a second lytic substance (complement) present in fresh serum.

These historical points account for why lysis became linked to the complement system and why the study of antibody and complement dominated the field of immunology for the next half century. Of interest, the first autoimmune disease to be recognized was only a few years later. It was a hemolytic anemia (paroxysmal cold hemoglobinuria) in which the same pair of reactants, antibody and complement, were shown to mediate RBC lysis.⁴ Consequently, this double-edged sword aspect of the complement system was recognized early, but not until the 1960s was there such a clear-cut demonstration of its protective versus injurious role. Compared with normal mice, C5-deficient mice were 100-fold more sensitive to death from pneumococcal infection but 100-fold less sensitive to tissue destruction by autoantibodies. Even more to the point, we now know that inherited deficiencies of C1, C4, and C2 strongly predispose to SLE, yet immune complex (IC) deposition and complement activation contribute to tissue damage in SLE.

FUNCTION

A major activity of the complement system is to modify membranes and tag antigens through covalent attachment of its activation fragments (Figure 23-1). For example, several million C3b molecules can bind to a bacterial surface in less than 2 minutes. One goal of these deposited complement proteins is to opsonize the target. C3b (and its degradation fragments) and C4b are ligands for complement

Figure 23-1 Function of the complement system. The most important function of the complement system is to alter the membrane of a pathogen by coating its surface with clusters of activation fragments. In one case, they facilitate the key process of opsonization, as C4b and C3b interact with complement receptors. In the other case, as with certain gram-negative bacteria and viruses, the membrane attack complex lyses the organism. The second critical function of complement is to activate cells and thus promote inflammatory and immune responses. The complement fragments C3a and C5a (known as *anaphylatoxins*) stimulate many cell types such as mast cells to release their contents and stimulate phagocytic cells to migrate to sites of inflammation (chemotaxis). Through these phenomena of opsonization and cell activation, complement serves as nature's adjuvant to prepare, facilitate, and instruct the host's adaptive immune response. Because complement activation occurs in a few seconds, this innate immune system initially engages most pathogens, especially those that try to enter the vascular space.

receptors on peripheral blood cells, tissue macrophages, and antigen-presenting cells such as follicular dendritic cells. Complement ligands and receptors are particularly adept at this coupling process, known as *immune adherence*. On phagocytic cells, this often leads to ingestion of the complement-coated infectious particle, IC, or cellular debris. Additionally, microorganisms (e.g., gram-negative bacteria) and host cells may be lysed by the terminal complement components (C5b-C9). Many microbes, though, possess capsules that make them resistant to lysis (e.g., most gram-positive organisms). In human diseases featuring autoantibodies, cells and tissues are similarly opsonized and membrane integrity can be compromised. A recent extension of this opsonic function relates to complement's role in the clearance of cellular debris following necrosis or apoptosis. In particular, one hypothesis to explain autoantibody formation in SLE is the complement system's failure to properly clear or handle apoptotic cells.⁵

A second function of the complement system is cellular activation.⁶ It prepares the local environment for defense against infection (see Figure 23-1). In the proteolytic steps of the early complement activation process, mediators that activate nearby cells are released. These low-molecular-weight fragments (C4a, C3a, C5a) are termed *anaphylatoxins* because, if released in excessive amounts, they induce shock. C3a and C5a, the two most powerful mediators, bind to their respective receptors at sites of complement activation. This causes histamine release by mast cells and chemotaxis to the area by phagocytic cells. With improved reagents and newer technology, receptors for C3a and C5a

have now been shown to be much more widely expressed than initially thought; for example, they are expressed by epithelial cells, T cells, hepatocytes, endothelial cells, neurons, and other cell types. C3a and C5a may engage their receptors on endothelial and neuronal cells to alter blood flow and modulate cellular function.

NOMENCLATURE

There are three activation cascades: the classical pathway (CP), the alternative pathway (AP), and the lectin pathway (LP) (Figure 23-2). They converge to activate C3 and then C5, leading to opsonization and membrane perturbation.

The nine proteins of the CP are designated by the uppercase letter C, followed by a number (Table 23-1). These components act in numeric order, except for C4, which is cleaved in parallel with C2 and before C3. Components of the AP are designated by capital letters (e.g., factor B). Regulatory proteins are designated by a descriptive title (e.g., C4 binding protein) or a letter (e.g., factor H) (Table 23-2). Single components or multimeric complexes that have enzymatic activity are designated by a bar (e.g., C1s). The loss of hemolytic potential by a component is usually designated by a lowercase prefix (e.g., iC3b). Fragments generated during complement activation are designated by a lowercase letter suffix (e.g., C3a, C3b). Except for the fragments of C2 (which are the opposite), the "a" fragment is liberated into the surrounding milieu, whereas the "b" fragment becomes cell bound and continues the cascade.

ACTIVATION CASCADES

Because many rheumatic diseases feature autoantibodies and therefore ICs, an understanding of the general principles of the activation cascades is essential to characterizing complement's role in a disease such as SLE^{3,7-10} (Figure 23-3; see also Figure 23-2).

Classical Pathway

The CP is activated primarily by ICs and a few other substances including C-reactive protein.¹¹ Human IgM and IgG subclasses 1 and 3 efficiently activate the CP. Once C1 is

Figure 23-2 Simplified diagram of the three pathways of complement activation. Deposition of clusters of C3b on a target is the primary goal. As shown by the broken line, the alternative pathway also serves as a feedback loop to amplify C3b deposition (regardless of which cascade deposited the C3b).

Table 23-1 Components of the Complement Activation Cascades

Component	Serum Concentration (µg/mL)	Function
Classical Pathway (CP)		
C1	50	Binds IC to trigger CP
C1q subcomponent		Binds Fc portion of IgG, IgM
C1r subcomponent		Protease: cleaves C1s
C1s subcomponent		Protease: cleaves C4 and C2
C4	200-500	Opsonin* (C4b), C4a [†]
C2	20	Protease: cleaves C3 and C5 as part of the convertases
Lectin Pathway (LP)		
MBL	150 (wide range)	Binds sugars to trigger LP
MASP-1/3	5	Proteases
MASP-2	5	Protease: cleaves C4 and C2
Alternative Pathway (AP)		
Factor D	1-2	Protease: cleaves factor B
Factor B	150-250	Protease: cleaves C3 and C5 as part of the convertases
Properdin	25	Stabilizes AP convertases
Central protein		
C3	550-1200	Opsonin [†] (C3b), C3a [†] ; convertases
Terminal Pathway (TP)		
C5	70	MAC component (C5b), C5a [†]
C6	60	MAC component
C7	60	MAC component
C8	60	MAC component (pore formation)
C9	60	MAC component (pore formation)

*C4b forms part of the CP C3 and C5 convertases. It anchors the enzyme complex to the target. Likewise, for the AP C3 and C5 convertases, C3b anchors these enzyme complexes to the target.

[†]C4a, C3a, and C5a are liberated on cleavage of C4, C3, and C5.

IC, immune complex; Ig, immunoglobulin; MAC, membrane attack complex; MASP, mannose-binding associated serine protease; MBL, mannose-binding lectin.

bound through the Fc portion of IgG or IgM interacting with the C1q subunit of the C1 complex (Figure 23-4), the C1r enzymatic subcomponent autoactivates by proteolysis and then cleaves C1s to C1s. C1s cleaves C4 to C4b, releasing the C4a fragment (Figure 23-5). The C4b fragment, having had its thioester bond disrupted, now has the transient ability (a few microseconds) to covalently bind to a

hydroxyl or amino group on a nearby target. C2 is also a substrate for C1, and C2 is cleaved by C1 to yield C2a and C2b. C2a interacts with 10% to 20% of the target-bound C4b to form the CP C3 convertase C4bC2a (Figure 23-6). The enzymatic or catalytic domain of this complex is C2a, which cleaves C3 to form C3a and activated C3b (Figure 23-7). Activated C3b, like C4b, has a few microseconds to

Table 23-2 Complement Regulatory Proteins

Protein	Tissue Distribution	Function	Disease Association
C1 inhibitor	Plasma	Inactivates C1r, C1s, and MASPs; a SERPIN	Hereditary angioedema
Factor I	Plasma	Cleaves C3b and C4b; requires a cofactor protein	Infections (secondary to low C3), HUS*
Membrane cofactor protein	Most cells	Cofactor for cleavage of C4b and C3b	HUS*
Decay-accelerating factor	Most cells	Decays C3 and C5 convertases	PNH
C4-binding protein	Plasma	Cofactor for cleavage of C4b; decays CP C3 and C5 convertases	None [†]
Factor H	Plasma	Cofactor for cleavage of C3b; decays AP C3 and C5 convertases	Infections (secondary to low C3), HUS,* type II MPGN, AMD
S protein (vitronectin)	Plasma	Blocks fluid-phase MAC	None [†]
CD59	Most cells	Blocks MAC on host cells	PNH
Anaphylatoxin inactivator	Plasma	Inactivates C3a, C4a, and C5a	Urticaria, angioedema

*Most patients with HUS are heterozygous for function-altering mutations.²²

[†]Insufficient number of cases of complete deficiency described to establish an association.

*Complete deficiency has not been reported.

Receptors were named in order of their discovery but are also commonly identified relative to their ligand specificity and CD number (see Tables 23-3 to 23-5). For example, complement receptor type 1 may be referred to in the literature as CR1, the C3b/C4b receptor, the immune adherence receptor, or CD35.

AMD, age-related macular degeneration; AP, alternative pathway; CP, classical pathway; HUS, hemolytic uremic syndrome; MAC, membrane attack complex; MASP, mannose-associated serine protease; MPGN, membranoproliferative glomerulonephritis; PNH, paroxysmal nocturnal hemoglobinuria; SERPIN, serine protease inhibitor.

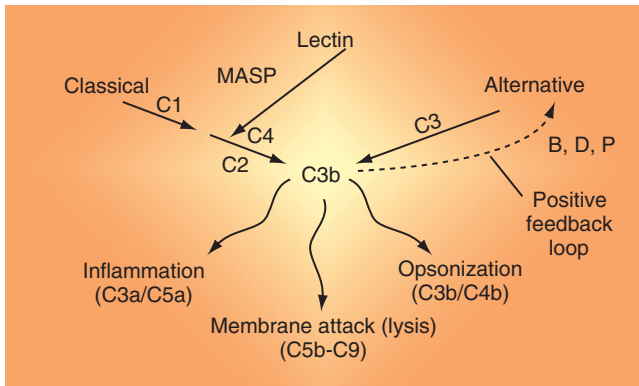

Figure 23-3 The complement activation pathways. Note that C4 and C2 serve identical purposes in the classical pathway (CP) and the lectin pathway (LP). They are cleaved by mannan-associated serine protease-2 (MASP-2) in the LP and by C1 in the CP. The convertases that cleave C3 are shown in Figure 23-6. C1 connects immune complexes to the CP as the C1q subcomponent binds to the Fc of antibody and the C1s subcomponent cleaves C4 and C2. In the LP, the lectin carries a MASP that cleaves C4 and C2.

attach to a target by binding covalently to a hydroxyl group (analogous to the interaction of C4b with a hydroxyl or amino group), where it serves as the major opsonin of the complement system. In addition, some of the newly activated C3b binds covalently to a specific region on the C4b component of the C3 convertase to form the CP C5 convertase, C4bC2aC3b (see Figure 23-6).

CP activation by polyclonal antibodies is efficient on membranes of cells, bacteria, and viruses. In one illustrative study, complement activation by IgG binding to a membrane antigen of a nucleated cell produced about 2.5 million bound C4b molecules, and about 0.5 million C2a molecules subsequently attached to these C4bs to form convertases.¹² In less than 5 minutes, 21 million (representing a 10× amplification over the number of attached C4b molecules) C3b molecules were deposited. Further, only about 10% to 20% of the C4b and C3b molecules generated bound to the target. The rest were inactivated by hydrolysis in the fluid phase and then degraded by fluid-phase inhibitors. Concomitantly, C4a, C3a, and C5a anaphylatoxins were generated equal to the number of C4b, C3b, and C5b

Figure 23-4 Similarity of C1q and mannose-binding lectin (MBL) structure. Ficolins, surfactins, and other members of the collectin family of proteins also share this general structure. Many activate the lectin pathway on interaction with ligand. The C1r and C1s in the case of the classical pathway and mannan-associated serine protease-2 (MASP-2) in the case of the lectin pathway are wrapped around the stalk of these tulip-like structures. It is the nonantigen or Fc portion of immunoglobulin IgG and IgM that engage the C1q subcomponent of C1.

Figure 23-5 C4 activation and degradation. The boxed activation fragment is covalently attached to the target. The other fragments are released into the surrounding milieu. C4a is a weak anaphylatoxin but has direct killing activity for bacteria. Factor I is a serine protease and cannot cleave C4b at a specific site unless accompanied by a cofactor protein. In the plasma, C4bp serves this role; on cells, it is a function of MCP (CD46) or CR1 (CD35).

fragments produced. Approximately 1 million membrane attack complexes (MACs) were formed. Interaction of the complement system with soluble antigens is a less efficient process, particularly the formation of the C3 and C5 convertases.

A single IgM molecule can activate the CP. In contrast, two IgG molecules in close proximity (side by side) are required before C1 can be bound. On erythrocytes, this means that several thousand IgGs must bind to an antigen before activation can occur. Consequently, antigenic density and display play a role in determining whether complement is activated. For example, in warm antibody (IgG)-mediated autoimmune hemolytic anemia, complement is usually not fixed (despite the autoantibody's being of an appropriate IgG subclass) because of low antigenic density.

Lectin Pathway

Lectins are carbohydrate-binding proteins^{5,13-15} (see Figure 23-4). They were initially described as proteins capable of agglutinating RBCs. They are important players in innate immunity and in rheumatic diseases. In particular, mannose-binding lectin (MBL) is a hepatocyte-synthesized plasma protein that preferentially binds to repeating mannoses and certain other repeating oligosaccharides of pathogens. MBL resembles C1q (it belongs to the same family of proteins, known as collectins), consisting of an oligomer with a terminal collagenous domain on one end and a globular domain on the other (see Figure 23-4). The main difference is that the carboxy terminus of MBL possesses a carbohydrate-recognition domain, whereas C1q has an Ig-binding domain.

Convertase	Classical/Lectin	Alternative
C3	C4bC2a	C3bBbP
C5	C3b C4bC1a C2a	C3b C3bBbP

Figure 23-6 Proteins of the C3 and C5 convertases. C4b or C3b anchors the enzyme complex to the target. The catalytic domains are the serine proteases C2a and Bb. The C3 convertase becomes a C5 convertase when a C3b attaches to a preferred acceptor site on C4b or C3b. Properdin (P) stabilizes the alternative pathway convertases.

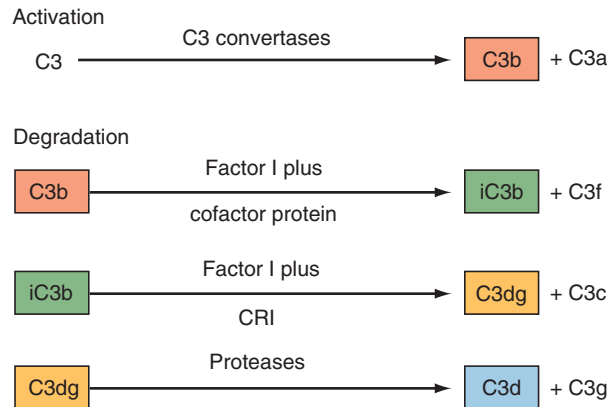

Figure 23-7 C3 activation and degradation. The boxed activation fragment is covalently attached to the target. The other fragments are released into the surrounding milieu. C3a is a potent anaphylatoxin and also kills bacteria directly. C3f may be a bone marrow-mobilizing factor for neutrophils. C3c and C3g have no known function.

Like C1q binding to the Fc portion of IgG, MBL engagement with its sugar ligand leads to activation of serine proteases similar to C1r and C1s, called *mannose-associated serine proteases* (MASPs). MASP-2 cleaves C4 and C2. MBL was discovered during an investigation into the cause of bacteremia in young children. MBL deficiency may be a predisposing factor for SLE and RA and contribute to a more severe disease phenotype.

The LP shares many features with the CP.^{8,9,13,14} The differences occur during the first few steps when MBL binds to an activating surface such as bacteria with the appropriate repeating oligosaccharides. Each element of the MBL-MASP complex is structurally and functionally homologous to the corresponding elements in the CP. C1q and MBL have globular ends through which they attach to their respective substrates. The MASP-2 in the complex cleaves C4 to form C4a and C4b (see Figure 23-5) and C2 to form C2a and C2b—identical to C1 cleaving C4 and C2. The C4b2a complex is the same as the C3 convertase generated in the CP (see Figure 23-6). The LP is a key player in innate immunity, where MBL and related lectins such as surfactants and ficolins bind to their cognate residues on microbes to trigger complement activation. At one time, MASPs (and possibly C1) directly activated C3, but through the evolution of C4 and C2, a more efficient C3 activating process was engineered.¹⁴

Alternative Pathway

The AP was the second complement activation pathway discovered (hence the name), but it is phylogenetically the most ancient.^{1,2} In contrast to the CP and LP, the AP does not require antibody or a lectin to be triggered. It likely plays a larger role in rheumatic diseases than previously appreciated because of its so-called feedback or amplification loop.¹⁶ Thus if C3b is deposited on a target by the CP or LP, the AP can enhance C3b deposition many-fold. The AP is also continuously active at a low level (like an idling car). The plasma inhibitors factor H and factor I and host cell surface regulators keep the system in check. In the absence of these regulators, as exemplified by inherited

deficiencies, the system fires to exhaustion. The AP routinely “kicks into gear” in the setting of microbes. If C3b deposits on an activating surface (i.e., one that lacks regulators), the system’s feedback loop allows several million C3b molecules to be deposited in a few minutes. In this pathway, factor B, structurally and functionally homologous to C2, binds to the deposited C3b, and is then cleaved by the active factor D to Bb and Ba. C3bBb is the AP C3 convertase (see Figure 23-6). It is stabilized by properdin (P), increasing the half-life of the enzyme 5- to 10-fold. The catalytic serine protease Bb of the C3bBbP enzyme complex then cleaves C3 to C3a and C3b; thus a feedback loop is set up. Some of the newly generated C3b molecules bind covalently to C3b already deposited on the target to form a C5 convertase (C3b₂Bb). In vivo, the C3 and C5 AP convertases are short-lived owing to spontaneous decay, unless stabilized by properdin. Two new developments in the AP are that (1) MASP 1/3 appears to be required to activate pro-factor D to factor D¹⁷ and (2) properdin may bind to certain targets to then serve as a platform to initiate the AP.¹⁸

Membrane Attack Complex

The terminal pathway begins with the cleavage of C5 by either the CP/LP or the AP C5 convertase. The liberated C5a fragment is a potent cell activator and chemotactic factor. The C5b binds C6, which in turn engages C7 to yield the fluid phase C5b67. This lipophilic complex can now interact with cell membranes. Following membrane insertion, it next binds C8. The C5b678 complex forms an initial pore in the plasma membrane and then recruits multiple (5 to 10) C9 molecules to yield C5b6789n. This complex is an efficient membrane channel former and is responsible for cell lysis. Many organisms and cell types are not easily lysed, however. The MAC also has multiple nonlytic effects on cells. The majority of these lead to activation of signaling pathways, as has been seen in the case of neurons and kidney cells. Some of the organ dysfunction observed in SLE, especially if transient or correctable with treatment, may be secondary to these nonlytic effects of the MAC.

REGULATORS

Physiologic Regulation

Unregulated, the complement system would fire to exhaustion, as illustrated by a complete deficiency of plasma regulatory proteins (factor H or factor I).¹⁹⁻²¹ The complement system has evolved to allow unimpeded activation on a microbe but to limit the process in time and space. The reaction must be finite in time to avoid excessive consumption of components in any one reaction and finite in space to minimize damage to surrounding host tissue. Thus a typical complement reaction on a microbial target occurs within a few minutes, and during this time, self-tissue is protected by plasma and membrane regulators. Many of these inhibitors act at the critical step of convertase formation. The convertase enzyme complexes intrinsically have short half-lives, and many of the inhibitors act to prevent their formation or to dissociate (decay) already formed complexes.

Fluid-Phase and Membrane Inhibitors

These regulators function at the initiating step (see Figure 23-3), the formation of the C3 and C5 convertases (see Figure 23-6), and the insertion of the MAC. The plasma inhibitors prevent fluid-phase activation (no target), whereas the membrane inhibitors prevent activation on healthy self-tissue (wrong target). The plasma inhibitors may also bind to damaged cells and extracellular matrices, where they now serve as a membrane regulator.^{8,9,22,23}

C1 inhibitor, a serine protease inhibitor (SERPIN), binds to C1r and C1s and to MASPs. The C1 complex is thereby disrupted, leaving C1q bound to antibody in the IC. C1q may then interact with C1q receptors to facilitate clearance of the IC.^{24,25} C1 inhibitor also prevents excessive and chronic fluid-phase C1 activation.²⁶ The C3 and C5 convertases are regulated by a family of proteins that include the membrane proteins decay-accelerating factor (DAF or CD55) and membrane cofactor protein (MCP or CD46) and the serum inhibitors C4-binding protein and factor H.^{8-10,19-21} These proteins act in three ways: prevent convertase assembly, disassemble convertases (decay-accelerating activity; Figure 23-8A), and serve as cofactors for the proteolytic inactivation of C4b and C3b (cofactor activity; Figure 23-8B). The cleavage is mediated by the plasma serine protease factor I. The MAC is also regulated by plasma and cell-anchored protein. CD59 is a widely expressed glycolipid-anchored membrane protein that binds C8 and C9 to prevent their membrane insertion, while the plasma protein vitronectin (S protein) inactivates fluid-phase MAC.

As a result of this regulatory activity, complement attack is focused on foreign surfaces (which usually lack complement regulators) and is held in check on host cells and in body fluids. Interestingly, a number of microorganisms have “captured” complement regulators (e.g., pox viruses) or have evolved proteins (herpesviruses) that inhibit complement activation (virulence factors).²⁷ However, the activation of the CP by antibody is rapid and efficient, such that the inhibitors generally have modest effects on limiting damage by complement-fixing antibodies. The host inhibitors are particularly efficient at preventing fluid-phase activation, activation on normal self, or amplification via the feedback loop.

COMPLEMENT RECEPTORS

The complement system exerts many of its effects through receptors (Tables 23-3 to 23-5). During the activation process, target-bound and released fragments serve as ligands

Figure 23-8 Regulation of convertases. **A**, Classical pathway C3 convertase. Decay-accelerating factor (DAF) irreversibly displaces the protease C2a from the anchoring piece C4b. C4b is cleaved by factor I. This reaction requires a cofactor protein, membrane cofactor protein (MCP); C4bp in plasma and CR1 also serve this role. The residual bound C4d has no known biologic activity. Classical pathway C5 convertase is similarly inactivated. **B**, Alternative pathway C3 convertase. The alternative pathway C3 and C5 convertases are disassembled in a similar fashion by DAF and MCP. In the case of C3b, it is cleaved to iC3b and then to C3dg. iC3b, C3dg, and C3d serve as adjuvants to promote an immune response. They accomplish this by reacting with the complement receptors on follicular dendritic cells and B lymphocytes. These activities of decay accelerating activity and cofactor activity are synergistic in their control of the convertases. They prevent complement activation in blood and on normal host cells and tissues.

Table 23-3 Receptors for C3 and C4

Receptor	Primary Ligand	Location	Function
CR1	C3b/C4b	Peripheral blood cells (except for most T cells and platelets), FDCs, B cells, podocytes	Immune adherence > phagocytosis; antigen localization and retention; complement regulation
CR2	C3dg/C3d	B lymphocytes, FDCs	Co-receptor for signaling through B cell receptor; antigen localization and processing
CR3/CR4	iC3b	Myeloid lineage	Phagocytosis > adherence

The CD numbers are as follows: CR1, CD35; CR2, CD21; CR3, CD11b/CD18; CR4, CD11c/CD18. FDC, follicular dendritic cell.

Table 23-4 Receptors for Anaphylatoxins

Receptor	Ligand	Location	Function
C3aR	C3a	Myeloid lineage including mast cells; smooth muscle, epithelial, endothelial, and neuronal cells	Cell activation, including granule exocytosis, upregulation of adhesins, chemotaxis, cytoskeletal effects
C5aR	C5a	Similar to C3aR	Similar to C3aR, but with more chemotactic effects

for complement receptors. For example, the vasomodulatory and chemotactic effects of C3a and C5a are due to interaction with their respective receptors. The opsonic fragments C4b and C3b mediate clearance of ICs and bacteria through adherence to and phagocytosis by CR1. Degradation of C3b by regulators leads to the formation of iC3b and then C3dg, which in turn interact with CR3/CR4 and CR2, respectively.

CR1 plays an important role in IC clearance. On erythrocytes, CR1 binds C3b/C4b-coated ICs (the immune adherence phenomenon) for processing and transport to the liver and spleen.²⁸ In these organs, the ICs are transferred from the erythrocyte to tissue macrophages, allowing the erythrocyte to return to the circulation for another round of clearance. CR1 on granulocytes and monocytes binds and ingests ICs, whereas CR1 on B lymphocytes, tissue macrophages, and follicular-dendritic cells facilitates trapping and processing of IC in lymphoid organs. CR2 is expressed by B lymphocytes and follicular-dendritic cells, where it facilitates antigen trapping and is a coreceptor for activation of the B cell antigen receptor.²⁹ Several new receptors for C3-bearing ICs have been described.^{30,31} The characterization of C1q receptors remains problematic, but they are likely important in the proper handling of antigens that have undergone complement activation on their surface.³²

COMPLEMENT IN THE INNATE AND ADAPTIVE IMMUNE RESPONSES

Innate Immunity

The complement system is the major humoral mediator of innate immunity. Toll receptors and their relatives comprise the major cellular arm of innate immunity. The complement system is activated by at least three mechanisms that are *independent* of an adaptive immune response (Table 23-6): natural antibodies, lectins, and the AP itself (Figure 23-9). Complement activation is therefore one of

the earliest reactions to microbes at sites of infection. The complement response opsonizes organisms for adherence, phagocytosis, and antigen processing while releasing fragments that activate immunocompetent cells and trigger an inflammatory milieu.

Adaptive Immunity

As pointed out earlier, complement was discovered because of its role as an effector (lytic) arm of humoral immunity. IgM and IgG subclasses 1 and 3 efficiently activate the CP. More recently, an important role for complement on the afferent side has been “rediscovered.”^{33,29}

Accumulating evidence indicates that complement is an instructor of the adaptive immune response. Nearly 30 years ago, the injection of cobra venom factor was used to destroy an animal’s complement activity. In such an experimental model, a requirement for complement in an animal’s normal immune response was clearly demonstrated. An attenuated IgM response, a lack of class switching from IgM to IgG, and a failure to generate memory B cells were features of a complement-deficient animal. Similarly, in multiple subsequent studies, C4- or C2-deficient guinea pigs and humans were shown to have a defective response to the intravenous administration of a phage antigen. Although they produced IgM antibody, these two species did *not* class-switch from IgM to IgG or demonstrate immunologic memory. In other studies, blocking CR2 reduced the antibody response to T cell-dependent antigens and prevented isotype switching. Further, animals with a targeted gene deletion of CR1/CR2 also had a lower IgM response and failed to isotype-switch. If larger doses of antigen or antigen plus adjuvants were administered, the complement-deficient animals responded normally. Finally, coating of antigen with C3d increases its immunogenicity up to 10,000-fold.^{29,33,34} Consequently, vaccines containing complement-coated antigens are likely to be more immunogenic. Taken together, these data indicate a contribution of the complement system (nature’s adjuvant) to an adaptive immune response.

Table 23-5 Receptors for C1q

Receptor	Ligand	Location	Function
CD91	Collagen-like region	Phagocytic cells	Enhance phagocytosis
CD93	Collagen-like region	Cell surface; monocytes, platelets, endothelial cells, neutrophils	Enhance phagocytosis
Calreticulin	Globular head	Intracellular	Bridge between C1q and CD93 and CD91
CR1	Globular head	Hematopoietic cells	Adherence
Others	Globular head	CR1	Probably facilitates adherence

CR1, complement receptor 1 (CD35).

Table 23-6 Complement System in Immunity

First line of defense as part of the innate immune response (takes place within seconds)
Mediates inflammatory responses
Modifies membranes of microbes
Instructive role to adaptive immunity
Facilitates antigen identification, processing, transportation, and retention
Activates cells to synthesize co-stimulatory molecules and to secrete cytokines and other mediators of an immune response; lowers threshold for B lymphocyte activation
Effector arm of humoral immunity ("complements" antibody)
Recognition of injured, apoptotic, and necrotic cells to enhance cleanup, proper disposal, and wound healing
Recognition of extracellular debris (crystals, pigments, lipids, proteins)*

*Examples are urate crystals, gout; lipofuscin pigments, drusen in age-related macular degeneration; oxidized lipids, atherosclerosis; and amyloid, Alzheimer's disease.

CLEARANCE OF NECROTIC AND APOPTOTIC CELLS

The complement system likely plays an important role in facilitating the removal of injured cells and cellular debris.^{5,9,35} Natural antibodies, lectins, and the AP recognize certain altered surface characteristics of damaged cells and, through opsonization, promote their proper removal. Such a system probably evolved to efficiently remove injured tissue, especially traumatized skin and apoptotic cells. In this process, a second goal is to avoid an immune response. If this system fails, as might happen in C1q or C4 deficiency, the individual is predisposed to developing autoantibodies (the so-called garbage- or waste-disposal hypothesis to explain autoimmunity in SLE). Ischemia-reperfusion injury is a related situation in which complement activation has clearly been shown to mediate damage to viable but at-risk tissues.³⁶ Altered cellular debris engages the innate immune system. Examples are urate crystals in gout, amyloid proteins in Alzheimer's disease, oxidized lipids in atherosclerosis, and lipofuscin (pigments) in age-related macular degeneration. In these chronic processes, relatively minor changes in complement regulatory activity may accelerate tissue damage. This has been shown most clearly in age-related macular degeneration, where about 50% of the genetic risk appears to be due to a subtle loss of regulatory function in a polymorphic variant of factor H.³⁷

Figure 23-9 Activation of the complement system in innate immunity. Shown are three means of complement activation in a nonimmune host. Other means such as a serine protease (e.g., thrombin) directly cleaving C5 have been described. (From Huber-Lang M, Sarma JV, Zetoune FS, et al: Generation of C5a in the absence of C3: a new complement activation pathway, *Nat Med* 12:682–687, 2006; and Amara U, Rittirsch D, Flierl M, et al: Interaction between the coagulation and complement system, *Adv Exp Med Biol* 632:71–79, 2008.)

IMMUNE COMPLEX CLEARANCE

The complement system is important for the processing and clearance of ICs.^{7-10,28,38} As ICs form, activation of the CP leads to C4b and C3b deposition, which in turn prevents the ICs from precipitating in a vessel wall or at a tissue site (called *maintenance of IC solubility*). The deposition of C3b on the antibody and antigen reduces the antibody's ability to cross-link and thereby precipitate ICs. Even preformed ICs can be solubilized by exposure to fresh serum. Soluble ICs bearing clusters of C3b become bound to peripheral blood cells, especially erythrocytes (immune adherence). Erythrocytes possess more than 80% of the CR1 in blood. They serve as a "taxi" or "shuttle" to transport ICs to the liver and spleen, where they dissociate from the RBCs. Most such ICs are then destroyed by macrophages in the liver or spleen. This transfer of ICs from the red cells to tissue macrophages may be mediated by simple affinity differences because tissue monocytes or macrophages possess multiple types of C3 and Fc receptors. Further, there is evidence for a proteolytic cleavage event at tissue sites that occurs near the stalk of CR1 to release ICs. The RBCs return to the circulation, possibly minus a few complement receptors, but ready for another round of immune adherence. This processing system for ICs evolved to prevent ICs from depositing in undesirable locations such as the kidney glomerulus. This clearance process could fail due to (1) a CP component deficiency, up to and including C3; (2) a complement receptor deficiency; (3) synthesis of a non-CP fixing antibody such as IgG₄ or IgA; (4) severe hepatic dysfunction; or (5) splenectomy.³⁸ This concept of IC clearance plays out in many infectious diseases and is especially pertinent to syndromes featuring ICs such as SLE, mixed cryoglobulinemia, serum sickness, and other vasculitic syndromes.

COMPLEMENT MEASUREMENT

Complement can be assessed by antigenic and functional assays (Tables 23-7 and 23-8). In clinical practice, the most common functional measurement is the total hemolytic or whole complement assay (THC or CH₅₀). The assay is based on the ability of the patient's serum sample to lyse sheep erythrocytes optimally sensitized with a rabbit antiship red cell antibody. All nine components of the CP (i.e., C1 through C9) are required for a normal THC. A result of 200 units indicates that at a dilution of 1:200, the test serum lysed 50% of the antibody-coated sheep erythrocytes in the reaction mixture. THC is a useful screening tool for detecting a homozygous deficiency of a single component (C1 through C8) because total deficiency of a component produces a result of less than 10 units or an undetectable THC. Deficiency of C9 results in a low but detectable THC. THC can screen for total deficiency and provide an overall assessment of complement activation. It is particularly recommended in the initial evaluation of most SLE patients and in the evaluation of patients with recurrent infections with encapsulated organisms, especially if the neutrophil count and Ig levels are normal.

Commonly used tests, especially to follow a patient's clinical course, are the antigenic assays for C4 and C3. They are simple, widely available, relatively inexpensive, and accurately carried out by nephelometric (turbidity)-based

Table 23-7 Assays for Complement Activation in Human Disease

Method	Use	Comments
CH ₅₀ or THC	Screen for component deficiency or activation of the classical pathway	Functional assay—requires appropriate sample handling
AP ₅₀	Screen for component deficiency or activation of the alternative pathway	Functional assay—requires appropriate sample handling
Antigenic (ELISA, immunodiffusion, nephelometry)	Standard method for C3, C4, factor B, C1 inhibitor, MBL, and factor H	Widely available (particularly in case of C4 and C3), easy to perform, reliable, inexpensive
Antigenic or hemolytic assay of an individual component	Further define a suspected deficiency	Samples usually sent to laboratories specializing in complement assays
Activation fragments C3a, C5a, Bb, C1r/C1s, C5b–C9 (neoantigen)	May be elevated in the setting of normal complement levels	Expensive; sample collection important; sent to commercial laboratories specializing in complement assays; more sensitive than assays of static levels
C1 inhibitor function	Clinical picture consistent with HAE, but C1 inhibitor levels by antigenic assay are normal or elevated	15% of HAE kindreds have normal or elevated levels of a nonfunctional protein
Immunofluorescence	Demonstration of complement fragments on cells and in tissues	C1q and cleavage fragments of C4 and C3 are most commonly analyzed, especially in kidney and skin biopsies
Antiglobulin testing (non-γ Coombs)	Demonstration of C3 fragments on erythrocytes in hemolytic anemias	Usual fragment detected is C3d

AP₅₀, alternative pathway equivalent; CH₅₀ or THC, total hemolytic assay for classical pathway; ELISA, enzyme-linked immunosorbent assay; HAE, hereditary angioedema; MBL, mannose-binding lectin.

immunoassays. They are useful in establishing the initial diagnosis of lupus and related syndromes and for following the clinical course of patients undergoing treatment, particularly if the concentrations were reduced when the disease process was active. On treatment, a return to normal values correlates with clinical improvement and bodes a better outcome. Table 23-8 provides examples of serum complement test results and their interpretation in rheumatic diseases.

Gaining in use are tests for the detection of activation fragments (e.g., C3a, C5a, C4d, C3d, Bb). Their clinical utility relates to the fact that they are dynamic parameters and thus reflect ongoing turnover of the system. Also, they are not as affected by partial inherited deficiencies or alterations in synthetic rates. However, they are more costly, not as widely available, more difficult to interpret, and unnecessary in most clinical situations. A potential advance in this area of biomarkers is the measurement of C4 and C3 fragments bound to RBCs, platelets, and lymphocytes.³⁹ Analogous to monitoring blood glucose by measuring HbA1c in

diabetes mellitus, the magnitude of complement activation is proportional to the quantity on the cell surface. Thus RBCs reflect disease activity over the past several months, whereas platelets reflect disease activity over the past week. Longitudinal studies are in progress to assess the utility of this approach in rheumatic diseases (primarily SLE) featuring complement activation.

COMPLEMENT DEFICIENCY

The complement system is the “guardian of the intravascular space” as it relates to bacterial infections.⁴⁰ Inherited deficiencies of complement activation components, particularly C3, predispose to local and systemic infections with encapsulated organisms (this was expected). However, the surprise was the susceptibility to autoimmunity, especially SLE^{8-10,35,41,42} (Tables 23-9 to 23-11). A thorough analysis of this subject has been published including tables listing every reported case of early complement component deficiency in humans.³⁵ Several other pertinent reviews are also

Table 23-8 Interpretation of Results of Complement Determinations

THC (units/mL)	C4 (mg/dL)	C3 (mg/dL)	Interpretation
150-250	16-40	100-180	Normal range
270	45	200	Acute-phase response (all are high); IL-1, IL-6, and TNF are major mediators to increase hepatic synthesis
100	10	80	CP activation (low C4 and C3). LP activation is rarely ever sufficient to lower basal levels outside of normal
100	30	50	AP activation (normal C4 and low C3)
<10 or 0	30	140	Inherited deficiency or in vitro activation*
50	<8	100	Partial C4 deficiency or fluid-phase activation†

*In vitro activation is more common than an inherited deficiency state. The lack of activity (THC < 10) in the setting of normal C4 and C3 antigenic levels suggests (1) an improperly handled sample, (2) cold activation (e.g., by cryoglobulins) following collection of the sample, or (3) homozygous component deficiency (most commonly C2 with a lupus presentation or, with a *Neisseria* infection, an AP or membrane attack complex component).

†Because THC is detectable, this cannot be a complete deficiency of C4. A partial C4 deficiency, such as of C4A, could give this result. Some types of immune complexes, especially cryoglobulins and a deficiency of the C1 inhibitor (hereditary angioedema), also give this pattern. In these cases, measurement of C2 is often helpful: A low value suggests activation, whereas a normal value suggests an inherited, partial C4 deficiency. Also, C4A and C4B alleles can be assessed by commercial laboratories.

AP, alternative pathway; CP, classical pathway; THC, total hemolytic complement or CH₅₀, whole complement titer.

Table 23-9 Clinical Manifestations of Complement Component Deficiency

Deficient Component	Clinical Syndrome*
Classical Pathway	
C1q	SLE, infections
C1r/C1s	SLE, infections
C4	SLE, infections
C2	SLE, infections
Lectin Pathway	
MBL	Infections
Central C3	Severe infections, GN, SLE
Membrane attack C5, C6, C7, C8, or C9	<i>Neisseria</i> infections
Alternative Pathway	
Properdin, factor D	<i>Neisseria</i> infections

*With early component deficiencies of the classical pathway (C1, C4, or C2), infections are caused by the commonly encountered pyogenic organisms. With a late component (C5-C9) or an alternative pathway component deficiency, *Neisseria* infections predominate, especially meningococcal infections.

GN, glomerulonephritis; MBL, mannose-binding lectin; SLE, systemic lupus erythematosus.

available.⁴²⁻⁴⁵ Most deficiencies are inherited as autosomal co-dominant (recessive) traits, except for the C1 inhibitor, which is autosomal dominant, and properdin and factor D, which are X-linked.

Classical Pathway

The prevalence of lupus in homozygous C1q, C4, or C2 deficiency is 90%, 75%, and 15%, respectively.^{35,42-45} The female-to-male ratio is approximately 1:1 in C1q or C4 deficiency but 7:1 in C2 deficiency. Concordance rates for SLE are 2% among dizygotic twins and 24% among monozygotic twins; concordance of SLE between siblings with C1q, C4, or C2 deficiency is 90%, 80%, and 58%, respectively. These complement-deficient individuals with SLE usually present before age 20 years and often have prominent cutaneous (90%) and renal (50%) manifestations. Antinuclear antibody tests are positive in about 75% of patients. Most patients are DNA negative, and antibodies to extractable nuclear antigens (especially antibodies to Ro) are detected in about 70%. The disease process tends to be

Table 23-10 Autoimmune Disorders in Complete Complement Component Deficiencies

Component	Number of Cases	Dominant Phenotype (%)	Other Phenotype*
C1q	35	SLE (94)	Infections
C1r/s	11	SLE (55)	Infections
C4	24	SLE (75)	Infections
C2	110	SLE (10-20)	Infections†
C3	21	Severe infections (75)	GN, SLE, vasculitis

*Infections may be the presenting manifestation and dominate the clinical course, particularly in C1q, C4, or C2 deficiency.

†In comparison to SLE, a smaller number of cases of Sjögren's syndrome, systemic sclerosis, Henoch-Schönlein purpura, and other immune-mediated syndromes have been reported with C2 deficiency.

GN, glomerulonephritis; SLE, systemic lupus erythematosus.

Table 23-11 Classical Pathway Complement Component Deficiency Leading to Autoimmunity

Two leading hypotheses exist; they are not mutually exclusive.

1. Defective immune complex handling:
For foreign antigens
For self-antigens (apoptotic and necrotic debris)
2. Defective immune responses:
Reduced humoral immune responsiveness
Failure to regulate autoreactive B cells

more severe in C1q and C4 than in C2 deficiency. Less than 1% of lupus patients have a complete complement component deficiency, with C2 deficiency being the most common.

About one third of SLE patients develop Abs to C1q. These antibodies probably develop after the onset of SLE and represent a secondary phenomenon.^{35,46} These patients tend to have renal disease and low complement levels (C4 and C3). Their value in diagnosis and in following patients' response to therapy are controversial.⁴⁷

The C4 genes are duplicated (all four must be deleted or defective to result in total C4 deficiency), giving rise to C4A (acidic) and C4B (basic) types.⁴⁸ C4A deficiency occurs in 10% to 15% of white SLE patients (compared with 1% to 3% of controls). Because C4A preferentially binds amino groups, it reacts more efficiently with some types of ICs than does C4B. This may explain why homozygous C4A deficiency is an independent risk factor for SLE. The association generally occurs across multiple ethnic backgrounds, as well as in the European ancestral autoimmune haplotype (HLA-A1, C7, B8, C4AQ*0, C4B1, DR3, DQ2). The clinical course is similar to that of idiopathic lupus, but there may be less renal disease.⁴⁹⁻⁵¹ In fact, one group has argued for caution in the use of immunosuppressive therapy because of the generally favorable course of renal disease in most patients.⁴⁹ Assessment of the number of C4A and C4B genes is available through commercial laboratories.

The most common homozygous complement component deficiency is of C2, occurring in 1 in 10,000 to 20,000 white individuals.³⁵ SLE occurs in about 15% of homozygous C2 null individuals. Notable differences in the setting of C2 deficiency are fewer renal and central nervous system manifestations but more cutaneous (prominent photosensitivity) involvement, earlier age of onset, and higher frequency of anti-Ro antibodies. Heterozygosity for C2 deficiency (1% to 2% of the white population) does not appear to predispose to SLE.

Alternative Pathway

C3 deficiency is associated with recurrent pyogenic infections and, less commonly, glomerulonephritis. For the latter, antinuclear antibodies are usually not detected, and other systemic features of SLE are lacking. Deficiency of properdin, factor B (one case), or factor D (a few cases) is strongly associated with meningococcal infections but not autoimmunity.⁵²

Lectin Pathway

Polymorphisms producing low serum MBL are associated with SLE across several ethnic backgrounds. In one series,

the incidence of SLE was increased twofold in patients with MBL deficiency.⁵³ Interestingly, infectious complications, particularly severe pneumonias in association with immunosuppressive therapy, were more frequent in MBL-deficient patients. This combination of MBL and C4 deficiency may be a particularly strong predisposing factor for SLE. In RA, MBL deficiency may be a modest risk factor.⁵⁴ Of perhaps greater interest, MBL deficiency was associated with earlier age of onset, more severe erosive disease, and increased frequency of infectious complications during treatment. As more studies have been reported, these MBL associations have become controversial.

Acquired Complement Deficiency States

Lupus Paradigm

Acquired complement deficiency states usually result from accelerated consumption. For example, CP activation is observed in more than 50% of lupus patients. Generally, the more active the disease process, the more likely that complement levels will be low because consumption progressively outstrips the liver's synthetic capacity. Low complement values (C4, C3, or THC) in SLE are a poor prognostic factor and correlate with antibodies to native DNA, nephritis, and, overall, more severe disease. Complement deposition in tissue, especially in the glomerulus, assists in the diagnosis and classification of lupus nephritis. Antibodies to C1q occur in about 30% of SLE patients and are associated with low complement and renal disease.^{35,46} Patients with mixed cryoglobulinemia and some with Sjögren's syndrome, antiphospholipid syndrome, or vasculitis syndrome will follow the lupus paradigm of CP activation leading to low C4 and C3 that correlates with disease severity.

KEY POINTS: SYSTEMIC LUPUS ERYTHEMATOSUS AND RELATED SYNDROMES

C1q, C4, or C2 deficiency is a single-gene defect that causes SLE in humans (rare variant with a major effect).

Partial deficiency of C4 (namely, C4A) also predisposes to SLE.

Once autoantibodies are present and ICs are deposited in undesirable tissue sites such as the kidney, complement activation contributes to the inflammatory reaction and tissue damage.

Complement measurements are helpful in following lupus patients, particularly if C4 and C3 are low at the time of disease activity. If so, the levels usually increase in response to treatment and might become a useful marker of disease activity. However, this point must be established for each patient.

The complement system is activated in most SLE patients, even though serum levels are not always reduced. Evidence for this statement comes from the assessment of complement turnover studies; the measurement of activation fragments; and, most convincingly, the demonstration of complement fragments in more than 70% of patients on skin biopsy (the old lupus band test). Even in normal skin, C3 fragments are deposited at the dermal-epidermal junction.

Anti-C1q antibodies are present in about 30% of SLE patients and in about 70% of lupus patients with nephritis. They probably arise in response to the high quantities of complement-activating IC. They likely contribute to the hypocomplementemia that is common in such patients, as well as to glomerular damage.

In mouse models of SLE, decreased activity of the early components of the CP accelerate disease development, whereas deficiencies of the late components (C5 to C9) ameliorate disease severity. The literature is not easy to interpret because the models may or may not accurately reflect human disease, and the mouse complement system has many differences from its human counterpart. For instance, mouse complement is a less potent activating system overall, and Fc receptors seem to be responsible for more of the proinflammatory reaction in mice than in humans.

MODELS OF INFLAMMATORY DISEASE FEATURING COMPLEMENT ACTIVATION

In vivo models have primarily explored complement activation as a mediator of tissue damage and inflammation in diseases in which complement is an effector arm of humoral immunity.^{8-10,16} More recently, complement's role in promoting inflammation and cellular migration, enhancing the afferent limb of the immune response, and handling of debris has received much attention.

Deficient Animals

Before gene knockout mice were available, guinea pigs deficient in C4, C2, or C3; rats and rabbits deficient in C6; dogs deficient in C3; and pigs deficient in factor H had been characterized.³ Further, in the 1960s, many inbred mouse strains were shown to be deficient in C5. Experiments with these species established the double-edged sword aspect of the complement system. Thus the deficient animals were more sensitive to challenges with encapsulated bacteria but were more resistant to antibody-mediated tissue damage. They were also widely used to determine the role of complement of immunopathologic damage—namely the Arthus reaction, serum sickness, and Forssman shock. These models are each discussed as they demonstrate the range of reactions mediated by complement activation.

In the Arthus model, antibodies to a foreign antigen are raised and then the antigen is reinjected into the immune host. If the antigen is injected in a joint, ICs form in the joint space, complement is activated, Fc γ receptors are engaged, and an inflammatory reaction ensues. A transient and nondestructive acute arthritis develops, but if antigen is injected repeatedly, tissue damage can be induced.

In this and other models, emphasis has recently been placed on separating the effects of immune complexes working through Fc γ receptors (Fc γ Rs) on phagocytes and B cells from those induced by activating complement.^{3,16,55-58} For example, it had generally been believed that the Arthus reaction in several species was mediated by complement activation. Thus the immigration of neutrophils in this

process was thought to be caused primarily by the local formation of C5a (i.e., complement dependent). This concept was further investigated when it became possible to generate, by homologous recombination, mice with complement or Fc γ R deficiency. In the mouse, Fc γ RIII but not complement was required for the Arthus reaction in the skin. However, complement was critical in IC-mediated peritonitis in mice and IC-mediated lung disease in rats. Interestingly, complement is also of major importance in IC-mediated skin disease in guinea pigs and rats. To summarize, the species, tissue site of activation, genetic background, and undoubtedly additional factors are critical in determining the importance of complement versus Fc γ R in disease pathogenesis. In most cases, these two effector systems operate conjointly, both in the response to pathogens and in autoimmunity.⁵⁹

In the usual serum sickness model in the rabbit employing bovine serum albumin (BSA)–anti-BSA, a polyarthritis develops that is mediated by the deposition of IC in joints. In the preantibiotic era, a serum sickness reaction was observed in patients receiving horse serum containing antibodies to treat infectious diseases. The human or rabbit clinical illness lasted 1 to 2 weeks, resolving as the host went into antibody excess and cleared the foreign protein. Of course, if more antigen was injected, an accelerated serum sickness reaction developed. These conditions may be met in SLE and in mixed cryoglobulinemia secondary to chronic hepatitis B or hepatitis C infection. In these conditions, nuclear antigens from cellular turnover and viral antigens synthesized in the liver are continuously present in a host with preformed antibodies.

Forssman antigen is a widely distributed lipopolysaccharide.³ Species that are Forssman negative such as the rabbit develop an immune response to the RBCs of sheep, a Forssman-positive species. Thus the rabbit responds to the injection of sheep RBCs with high-titer anti-Forssman antibody. On intravenous injection of this rabbit antibody into guinea pigs, a Forssman-positive species, the antibody travels to the lung, where it causes alveolar capillary fluid leakage and hemorrhage that is CP dependent. Phagocytes are not important in this cataclysmic reaction that causes death in a few minutes secondary to pulmonary edema. The MAC of complement is essential.

Gene-Targeted Deficiencies

Most components, regulators, and receptors have now been deleted by gene-targeted insertional mutagenesis.^{7-9,16,42,60,61} C1q, C4, C2, C3, and CR1/CR2 mice demonstrate substantial defects in T cell–dependent immune responses and have the expected defects in IC clearance. Thus for most strains with a defect in the CP or AP, defective clearance of bacteria and viruses was shown. The C1q- and C4-deficient mice (depending on the genetic background) are also predisposed to autoimmunity including glomerulonephritis (lupus-like picture) and delays in the clearance of apoptotic bodies. The C5aR-deficient mice have a decrease in inflammatory cell infiltrates. Although there are substantial differences between the human and mouse complement systems, these mice have been useful in clarifying complement's role in host defense against infection, the immune response, and autoimmunity.

Antiphospholipid Antibody Syndrome

The antiphospholipid syndrome is often associated with hypocomplementemia in the absence or presence of a positive test for antinuclear antibodies. In a recent review of a large number of such patients, hypocomplementemia was just as frequent as in patients with SLE.⁶² Complement activation is also a common event in recurrent fetal loss.⁶³ In a mouse model of antiphospholipid antibody–induced pregnancy loss, complement-deficient mice were protected from fetal loss.⁶⁴ Complement activation by the antiphospholipid antibody is a required intermediary event in the pathogenesis of fetal injury. In particular, complement activation by the autoantibodies is proposed to cause a dysregulation of angiogenic factors such as vascular endothelial growth factor.⁶⁵ Clinical trials are under way to assess the role of complement activation in patients with the antiphospholipid syndrome.

Complement Activation in Polyarthritis

Human Rheumatoid Arthritis

A long-standing observation in RA and juvenile RA is that the complement system is activated in the synovial fluid and surrounding joint tissue.^{16,66,67} Thus if the functional activity of joint fluid C4, C2, or C3 is determined, it is lower than expected on the basis of the antigenic level. Such data have established that complement components in RA joint fluid are commonly functionally inactive. In other words, the components have already been engaged in an immune reaction, and activation fragments are largely being measured. Further, essentially every complement activation fragment is elevated in RA joint fluid. The activation profile is primarily that of the CP (low C4 and C2), although there is also substantial evidence for contribution of the AP. Clinical correlations with measures of complement activation in RA include a more severe, erosive, and seropositive disease process. For approximately 3 decades (1950 to 1980), B cells, rheumatoid factors, and complement were postulated to play a predominant role in mediating the synovial inflammation in RA. Then, for the next 2 decades, T cell–mediated immunity was thought to be the predominant system responsible for the synovial reaction in RA. Today, a more prominent role for B cells, autoantibodies, and complement is again thought to exist; their critical role in animal models of RA has been recognized, and antibodies to citrullinated peptides have been identified. Both humoral and cellular immunity are required to produce a persistent synovitis in the RA syndrome.

KEY POINTS: RHEUMATOID ARTHRITIS AND RELATED SYNOVITIDES

Complement activation fragments are present in joint fluid and deposited in synovial tissue.

Autoantibodies (e.g., to citrullinated peptides) can activate the complement system and trigger inflammation.

Rheumatoid factors augment the effects of IgG bound to an antigen by promoting both agglutination of the immune complexes and further complement activation.

Low serum C4 and C3 are common in rheumatoid vasculitis, indicating classical pathway activation by immune complexes; similarly, cryoglobulins and other types of immune complexes activate the classical pathway.

In mouse models of rheumatoid arthritis featuring autoantibodies, complement inhibitors and complement deficiency protect against disease development and/or reduce its severity.

Collagen-Induced Arthritis

Complement activation products are prominent in the joint fluid and synovial tissue of rat and mouse models of collagen-induced arthritis.^{16,67-69} The disease is mild or absent in mice who are C5-deficient or treated with a function blocking monoclonal antibody to C5. Several complement inhibitors with activity against the convertases and factor B-deficient mice were also protected.^{60,70} These results implicate the AP in generating C5a, C5b to C9 (MAC), or a combination thereof as being responsible for synovitis. One might have predicted that C3 activation products would be major contributors to disease pathogenesis, but that was not the case in these models.

K/BxN Mouse Model

A spontaneous mouse model was generated by crossing the T cell receptor (TCR) transgenic mouse line (known as *KRNxC56BL/6*) with the nonobese diabetic (NOD) mouse strain.^{71,72} Autoantibodies that arise in the K/BxN mouse recognize the ubiquitously expressed enzyme glucose-6-phosphate isomerase. Important features of this model are (1) a destructive small-joint arthritis that resembles RA develops; (2) the autoantibodies are pathogenic, as the disease can be transferred to other strains by antibody alone; and (3) complement is required for the arthritis to develop. Surprisingly, the CP is not necessary; mice deficient in C1q or C4 are as susceptible as wild-type mice. Mice deficient in C3 or AP component factor B, however, do not develop arthritis. Moreover, C5-deficient mice or mice treated with a monoclonal antibody to C5 are resistant to the disease. C5a receptor-deficient mice are also protected from developing arthritis. These results implicate AP-derived C5a interacting with its receptor as being critically important to disease development.

Another insight from this model is a putative role for the complement regulatory proteins in “allowing” a local inflammatory process.⁷¹ Thus the pathogenic antibody in this model also binds to the kidney glomerulus, but there is no excessive complement deposition and no development of glomerulonephritis. A likely explanation is that both antigen accessibility and a permissive local environment for complement activation are required. Joint cartilage is relatively devoid of complement regulatory proteins. In this model, the AP is engaged but not the CP because the autoantibody is predominantly of the IgG1 subclass. In the mouse, this antibody subclass has poor complement-fixing ability through C1. Nevertheless, antibodies bound to an antigen can protect the cascade from regulation by inhibitors and thereby trigger the AP.⁷³ Though it remains unclear

why the autoantibody arises, this model has provided provocative insights into how an autoantibody- and complement-mediated inflammatory arthritis could occur in humans. Further, it has many parallels to human RA featuring anticitrullinated protein antibodies.⁷⁴

THERAPEUTIC IMPLICATIONS

The study of the complement system has undergone a renaissance. Much of this revival relates to (1) the development of inhibitors for experimental and clinical use; (2) the association of deficiency states with autoimmunity (especially the C1q, C4, C2 lupus association); (3) greater appreciation of the role of the innate immune system and its role in instructing the adaptive immune system; (4) the availability of gene-targeted mice to more precisely assess the role of complement in the normal immune response and in mouse models of autoimmunity; and (5) whole genome screens with single-nucleotide polymorphism analyses that have identified partial deficiencies and polymorphisms in complement regulatory proteins as causing a predisposition to atypical hemolytic uremic syndrome⁷⁵ and age-related macular degeneration.³⁷

The development of complement inhibitors for clinical use is a long-sought goal. One such compound, a humanized monoclonal antibody to C5, has been used successfully to treat a complement-mediated hemolytic anemia⁷⁶⁻⁷⁹ and atypical hemolytic uremic syndrome (aHUS). This monoclonal antibody (eculizumab) is now approved by the FDA to treat paroxysmal nocturnal hemoglobinuria (PNH) and aHUS. Both of these diseases feature illnesses in which there is a decrease in complement regulatory proteins. In PNH the hosts' RBCs are lysed by the alternative pathway, while in aHUS excessive alternative pathway activation on the glomerular endothelium leads to a hypercoagulative state. Now that it is in the marketplace, it will be tried in most diseases featuring autoantibodies that activate complement. This agent and many others in the pipeline ameliorate inflammatory responses in animal models, where considerable evidence has already been accumulated relative to complement's participation.⁸⁰ Complement inhibition, however, also reduced infarct size in experimental models of myocardial infarction and tissue damage in many other types of ischemia-reperfusion injury.³⁶ Further, a role for complement in clearing apoptotic cells is likely.³⁵ Characterizing the effects of complement inhibitors in clinical trials of several rheumatic diseases in humans is much anticipated.

KEY POINTS

Eicosanoid biosynthesis is catalyzed by cyclooxygenases and lipoxygenases.

Conversion of the endoperoxide intermediate prostaglandin H_2 requires activity of specific terminal synthases.

Eicosanoids and their receptors regulate inflammatory and immune responses.

Eicosanoid synthesis is modified by administration of precursor fatty acids.

The addition of oxygen to arachidonic acid and other polyunsaturated fatty acids not bound to membrane phospholipids in nearly all human cell types results in formation of several classes of bioactive products termed *eicosanoids*. These include prostaglandins (PGs), prostacyclin (PGI), thromboxanes (TXs), leukotrienes (LTs), and lipoxins (LXs). All of these compounds are crucial to the regulation of immunity and inflammation, among other physiologic and pathologic processes. Although eicosanoids are derived from C20 polyunsaturated fatty acids (eicosa = 20), only a small percentage of these polyenoic acids form the eicosanoids: dihomogamma linolenic acid (DGLA), which is 8,11,14-eicosatrienoic acid; arachidonic acid (AA), which is 5,8,11,14-eicosatetraenoic acid; and eicosapentaenoic acid (EPA), which is 5,8,11,14,17-EPA (Figure 24-1).

Two groups of fatty acids are essential to the body: the omega-6 series derived from linoleic acid (18:2 n-6) and the omega-3 series derived from α -linolenic acid (18:3 n-3). The *n* refers to the number of carbon atoms from the methyl (omega) end of the fatty acid chain to the first double bond (i.e., omega-3 and omega-6 designations). Using this notation, 18 refers to the number of carbon atoms in the fatty acid. The degree of unsaturation (the number of double carbon-carbon bonds) follows the number of carbon atoms. Fatty acids are metabolized by an alternating sequence of desaturation (i.e., removal of two hydrogens) and elongation (i.e., addition of two carbons). Membrane phospholipids are the main storage site for polyunsaturated fatty acids and are particularly rich in eicosanoid precursors, which are located at the sn-2 position (Figure 24-2). Because mammalian cells cannot interconvert n-3 and n-6 fatty acids, the composition of membrane phospholipids is determined by exogenous sources of fatty acids.

Prostaglandins, Leukotrienes, and Related Compounds

ROBERT B. ZURIER

BIOSYNTHESIS OF EICOSANOIDS

Phospholipases

Phospholipase A_2 (PLA $_2$) in lysosomes or bound to cell membranes catalyzes the breaking of the sn-2 bond, facilitating release of AA or other polyunsaturated fatty acids (see Figure 24-2). The enzyme is crucial to regulation of eicosanoid synthesis because it is in the nonesterified state that the polyunsaturated precursors enter into the cascades, leading to eicosanoid formation. Only a scant amount of oxidation at carbon 15 of AA occurs catalytically when the fatty acid is still covalently bound as part of a phospholipid.¹ More than 25 different PLA $_2$ isoforms have been characterized and grouped based on primary structure, localization, and Ca^{2+} requirements.² Cytosolic PLA $_2$ group IV is the major catalyst of arachidonate release that leads to PG and LT production. The structure of cPLA $_2$ reveals a monomeric cytosolic protein with a molecular size of 85 kD. Potent and selective inhibitors of cPLA $_2$ have been developed.³ Lysophospholipids “left over” after the action of PLA $_2$ are direct precursors of platelet-activating factor (PAF), a potent mediator of inflammation, which is generated by acylation (addition of fatty acid) in the open sn-2 position of the lysophospholipid. One member of the PLA $_2$ superfamily, lipoprotein PLA $_2$, may serve as a marker for cardiovascular risk.⁴

Four distinct types of PLA $_2$ activities hydrolyze fatty acids esterified at the sn-2 position: Secretory PLA $_2$ (sPLA $_2$) has small disulfide cross-linked proteins that require Ca^{2+} in mM concentrations for optimal activity. Cytoplasmic PLA $_2$ (cPLA $_2$) has larger proteins requiring Ca^{2+} in μ M concentrations, which are AA-selective and can deacylate diacylphospholipids completely, preventing accumulation of potentially toxic lysophospholipids. Ca^{2+} -independent PLA $_2$ (iPLA $_2$) exhibits specificity for plasmalogen substrates. Finally, PAF acetylhydrolase (PAF-PLA $_2$) has a series of isozymes specific for short chains.⁴

Under basal conditions, AA is liberated by iPLA $_2$ and then reincorporated into cell membranes (reacylated). It is unavailable for appreciable eicosanoid biosynthesis. The acylase enzymes competitively inhibit the cyclooxygenase (COX) isoenzymes. After receptor activation and cell stimulation, intracellular Ca^{2+} levels increase and the Ca^{2+} -dependent cPLA $_2$ liberates arachidonate at a rate that exceeds the rate of reacylation, leading to arachidonate metabolism by COX isoenzymes and by lipoxygenases (LO). Initial formation of PGE $_2$ seems to be due to preferential coupling among cPLA $_2$, COX-1, and cytosolic PGH-PGE isomerase. More intense inflammation leads to participation of secreted sPLA $_2$ and amplification of PGE $_2$ biosynthesis by inducible COX-2. It is an oversimplification to regard

Figure 24-1 Metabolic pathways of essential fatty acids. The pathways are ones of progressive desaturation alternating with elongation. Eicosanoid precursors include dihomogamma linolenic acid, arachidonic acid, and eicosapentaenoic acid. LT, leukotriene; PG, prostaglandin; TX, thromboxane.

availability of AA as the sole rate-limiting step in cellular eicosanoid biosynthesis. The coordinated action of phospholipases and the restricted expression and altered activation of COX isoenzymes are also important.⁵

Phospholipase C (PLC) hydrolyzes the polar head group (e.g., inositol, choline) from phospholipids to yield diacylglycerol (DAG) and the polar head group. Direct protein isolation and molecular-cloning studies have revealed multiple PLC isozymes in mammalian tissues. Phosphatidylinositol-PLC occurs in cytosolic (cPLC) and secreted (sPLC) forms and can be divided into three major classes (PLC- β , PLC- γ , and PLC- δ) based on substrate specificity. PLC with specificity for phosphatidylinositol and phosphorylated phosphatidylinositol is a key component of phosphatidylinositol-mediated signaling pathways. DAG is an activator of protein kinase C (PKC), and rapid production of this lipid by phosphatidylinositol-PLC hydrolysis of the phosphorylated phosphatidylinositol pool is a primary step in signaling. Further AA is made available by the sequential actions of diglyceride lipase and monoglyceride lipase.⁶ PLC with activity on phosphatidylcholine has also

been identified. Peripheral blood monocytes from patients with rheumatoid arthritis (RA) exhibit greater PLA₂ and PLC activity than cells from healthy volunteers. PLA₂ concentrations did not correlate with disease activity, but the greatest increases in PLC enzyme activity were seen in cells from patients with the most severe, persistent, proliferative disease, not in cells from patients with the most active disease at the time the cells were studied.⁷ In accord with the need for balance in regulation of the inflammatory response, sPLA₂, numbering nine members in humans, has both inflammatory and anti-inflammatory actions. Thus, group V sPLA₂ counters the inflammatory activity of group IIA sPLA₂ by regulating cysteinyl leukotriene synthesis and promoting immune complex clearance in a murine model of autoimmune erosive inflammatory arthritis. It is of interest that concentrations of IIA sPLA₂ are far greater than those of V sPLA₂ in synovial fluid from patients with RA.⁸ In keeping with the fact that nothing in biology and the pathogenesis of disease is simple is the observation that treatment of RA patients with sPLA(2)-IIA inhibitors has only transient benefit and that sPLA(2)-IIA has

activity (induction of COX-2) independent of its enzyme activity.⁹

Hydrolysis of phospholipids by phospholipase D (PLD) produces phosphatidic acid (PA) and the respective polar head groups. The capacity of cells to interconvert PA and DAG through the action of specific cellular phosphatases and kinases (Figure 24-3) suggests that AA release from DAG and a variety of intracellular signaling and protein-trafficking events may be regulated by PLD activity. The targets of phosphorylation within the PLD₂ molecule that are key to its regulation have been mapped. PLD may be activated after or independent of PLC activation.¹⁰

The tetraenoic precursor (AA) is the most abundant of the three precursor fatty acids in cells of individuals who eat usual Western-style diets. Metabolites of AA constitute the “2” series (dienoic) PGs (two double bonds in the molecule), and the metabolic pathway has acquired the familiar name “arachidonic acid AA cascade.” However, diets enriched in eicosapentaenoic or gamma-linolenic acid, the other eicosanoid precursors, lead to formation of different eicosanoids. Figure 24-4 illustrates the COX and 5-LO lipoxygenase pathways of the cascade.

Cyclooxygenase Pathway

The first step in the biosynthesis of the “prostanoids” (e.g., PGs, TXs, prostacyclin) is catalyzed by the bifunctional PG endoperoxide synthase isozyme (PGHS)-1 (COX-1) and PGHS-2 (COX-2). COX is a homodimeric enzyme that integrates into only a single leaflet of the lipid bilayer of the cell membrane. The COX active site is a long hydrophobic

Figure 24-3 Reactions catalyzed by phospholipases C and D, illustrating interconversion of diacylglycerol (DAG) and phosphatidic acid (PA).

channel. Aspirin and most other nonsteroidal anti-inflammatory drugs (NSAIDs) exclude arachidonate from the upper portion of the channel.¹¹ To form the characteristic five-carbon ring structure (TXs contain a six-member ring), the precursor fatty acids must have double bonds at carbons 8, 11, and 14 (numbering from the carboxyl group). When a molecule of oxygen is inserted across carbons 9 and 11, ring closure occurs enzymatically across C8 and C12, creating the unstable PG endoperoxide PGG. Subsequent peroxidation yields PGH with formation of the cyclopentane ring. PGH serves as the common precursor for PGs, prostacyclin, and TXs that are formed under the influence of terminal synthases (see Figure 24-4). In addition to the activity of phospholipases, regulation of PG synthesis also occurs at the level of PGHS gene expression. PGHS levels are increased by interleukin (IL)-1, platelet-derived growth factor, and epidermal growth factor, agents that increase PG synthesis.

Cell membranes constitute the source of substrate AA and the site of action of eicosanoid-forming enzymes. PG synthesis can also form at lipid bodies, which are non-membrane-bound, lipid-rich cytoplasmic inclusions that develop in cells associated with inflammation. Lipid bodies isolated from human monocytes express PGHS activity, are reservoirs of arachidonyl phospholipids, and can function as domains of PG synthesis during an inflammatory reaction.¹²

PGHS, the well-known target of NSAIDs, exists in two isoforms. These isoforms are similar in terms of amino acid identities (about 60%), catalytic properties, and substrate specificity, but they differ in their genomic regulation.¹³

Regulation of Cyclooxygenase-1 Expression

The gene for COX-1 (PTGS1) is preferentially expressed constitutively at high levels in selected cells including endothelium, monocytes, platelets, renal collecting tubules, and seminal vesicles. Because the expression level of the enzyme does not vary greatly, it has been difficult to study its transcriptional regulation. The gene has a TATA-less promoter that contains multiple start sites for transcription. It is also known that Sp1/Cis regulatory elements in the promoter bind the Sp1 transcription factor to induce COX-1 gene expression. In addition, COX-1 (COX-2) splice variants may function in tissue-specific normal and pathologic processes and may represent new targets for therapy.¹⁴ The localization of COX-1 in nearly all tissues

Figure 24-4 Cyclooxygenase pathway of arachidonic acid metabolism. MDA, malondialdehyde; PG, prostaglandins; TX, thromboxane.

under basal conditions suggests that its major function is to provide eicosanoids for physiologic regulation. This is seen clearly in platelets that do not have nuclei and cannot produce an inducible enzyme on activation. Rather, TXs are produced constitutively so that platelet aggregation can be completed.

Regulation of Cyclooxygenase-2 Expression

The regulated formation of eicosanoids implies that cells have an appreciable ability to amplify the rate and amount of eicosanoid synthesis. Several processes contribute to that regulation including silencing of sPLA₂ expression by COX-2 and autoinactivation (“suicide inactivation”) of COX-2 and other oxygenases and synthases. In addition, the COX-2 transcript contains at least 12 copies of the AUUUA RNA motif, which makes it unstable and subject to rapid degradation. Factors that regulate COX-2 expression are specific for the physiologic processes involved. Expression of COX-2 in the macula densa in the kidney depends on luminal salt concentrations. Transcriptional activation of the COX-2 gene by mediators of inflammation such as IL-1 β and tumor necrosis factor (TNF) is likely

regulated by the transcription factors nuclear factor κ B (NF κ B) and C/EBP. Perhaps the most crucial of the several demonstrated regulatory sequences in the 5' flanking regions of the COX-2 gene is the ATF/CRE, a site that is activated by the transcriptional activator protein-1 (AP-1) and the cyclic adenosine monophosphate (cAMP) regulatory binding protein. Now that quantitative polymerase chain reaction analysis is routinely used to examine gene expression, it is clear that COX-2 is constitutively expressed under basal conditions at levels too low to be detected by Northern blot analysis.¹⁵ Depending on cell and tissue specificity, several signaling pathways (kinases, Rho, cyclic guanosine monophosphate, Wnt) and transcription factors (NF κ B, AP-1, nuclear factor of activated T cells [NFAT]) are involved in COX-2 expression.¹⁶

COX-1 and COX-2 effect a balance in several physiologic and pathologic situations. Of particular interest are their actions in kidney and stomach. During times of low blood volume, the kidney releases angiotensin and other factors to maintain blood pressure by systemic vasoconstriction. Angiotensin also provokes PG synthesis in the kidney. COX-1, expressed in vessels, glomeruli, and collecting ducts, produces vasodilating PGs, which maintain renal

plasma flow and glomerular filtration during conditions of systemic vasoconstriction. In the antrum of the stomach, COX-1 leads to production of PGs, which increase gastric blood flow and mucus secretion. Inhibition of COX-1 by NSAIDs prevents these protective mechanisms and results in renal ischemia and damage and gastric ulcers (mainly antral) in susceptible individuals. These observations have led to development of NSAIDs that selectively inhibit COX-2 and spare COX-1. AA gains access to the active site of the COX via a hydrophobic channel, and access is blocked by insertion of an acetyl residue on Serine 530 in COX-1 and Serine 516 in COX-2. The irreversibility of the interaction and the unique expression of COX-1 in the anucleate platelet is the reason for the clinical efficacy of low-dose aspirin. Nonacetylated NSAIDs compete with arachidonate for the active site and can interfere with the sustained effects of aspirin. Although the structures of COX isozymes are similar, COX-2 is characterized by a side-pocket extension to the hydrophobic channel, which is where the selective COX-2 inhibitors localize.¹³

The major adverse effects of NSAIDs, gastroduodenal injury and impaired renal function, as well as the induction of myocardial infarction and stroke, are caused by inhibition of COX-1, whereas the analgesic and anti-inflammatory activities of NSAIDs rest in part on their ability to inhibit COX-2. COX-2 also seems to have a regulating role, however, in renal, brain, gastrointestinal, ovarian, and bone function. COX-2 is also expressed in endothelial cells, and its inhibition suppresses prostacyclin synthesis by endothelial cells.¹⁷ COX-2 acts in the initiation and the resolution of inflammation. Its expression increases transiently early in the course of carrageenan-induced pleurisy in rats. Later in the response, COX-2 is expressed at even higher levels, leading to synthesis of PGD₂ and its dehydration product 15-deoxy- δ 12,14-PGJ₂ (15 δ PGJ₂). Early expression of COX-2 is associated with production of inflammatory PGs, whereas the later peak results in production of PGs that suppress inflammation.¹⁸ That inflammation occurs in COX-2 knockout mice¹⁹ reminds us, as Lewis Thomas stated,²⁰ “inflammation will take place at any cost.” Nonetheless, the search for more selective and localized COX-2 inhibition goes on. One strategy is achieved by using the mechanism of RNA interference (RNAi). Nonpathogenic *Escherichia coli* are engineered to invade tumor cells (and perhaps could be designed to invade synovial cells) and to generate anti-COX-2 siRNA molecules (siCOX-2), thereby silencing overexpressed COX-2. The involvement of miRNAs in COX-2 posttranscriptional regulation suggests a possible endogenous silencing mechanism to reduce COX-2 expression.²¹

Cyclooxygenase-3

Acetaminophen, similar to NSAIDs, suppresses pain and fever. It is not an anti-inflammatory agent, and its mechanism of action—despite its extensive use—has not been apparent. The finding that acetaminophen inhibits COX activity more in canine brain homogenates than in spleen homogenates gave rise to the concept that variants of the COX enzyme exist that are differentially sensitive to acetaminophen. COX-3 is a splice-variant of COX-1 that retains the intron-1 gene sequence at the mRNA level,

which encodes a 30 amino acid sequence inserted into the N-terminal hydrophobic signal peptide of the enzyme protein. COX-3 protein and mRNA transcripts have been identified in human tissues as well as rats, most abundantly in cerebral cortex and heart, although the mechanism for conversion of COX-3 mRNA to active enzyme is not clear.^{11,22} These findings led to a search for other COX variants. A COX-2 variant induced by 0.5 mM diclofenac via stimulation of the nuclear receptor peroxisome proliferator-activated receptor (PPAR γ) (the receptor for the pro-resolving 15-deoxy- δ 12, 14 PGJ₂) has been discovered. Whereas induction of COX-2 by LPS results in release of the inflammatory cytokines IL-6 and TNF, diclofenac-induced COX 2 leads to release of the anti-inflammatory cytokines TGF beta and IL-10.

Prostaglandin Synthases

Conversion of the endoperoxide intermediate PGH₂ to PGs requires the activity of specific terminal synthases: Hematopoietic PGD synthase (H-PGDS) catalyzes the isomerization of PGH₂ to PGD₂ in immune and inflammatory cells. Cytosolic PGE synthase (cPGES) is responsible for constitutive expression of PGE₂, and microsomal PGE synthase (mPGES-1) induces PGE in response to inflammatory stimuli. At least 10 enzymes convert PG precursors into biologically active PGs.²³ Suppression of PG synthase activity might be considered as an alternative strategy that would fall between global blockade by inhibition of COX and blockade of a single eicosanoid receptor.²⁴ Increased fibrosis may now be added to the well-known adverse effects of NSAIDs including COX-2 selective agents.²⁵ Thus efforts have been directed at development of drugs that inhibit mPGES-1, rather than COX-2, thereby suppressing PGE₂ production while sparing production of prostacyclin.³ Microsomal PGES-1 is upregulated throughout development of the rat adjuvant-induced arthritis model.²⁶ Because PGE₂ is also important to induction of matrix metalloproteinases MMP-3 and MMP-13, suppression of mPGES-1 might counteract articular cartilage degradation in patients with inflammatory arthritis.²⁷

PRODUCTS OF THE CYCLOOXYGENASE PATHWAY

Prostaglandins

The basic structure of all PGs is a “prostanoid acid” skeleton, a 20-carbon fatty acid with a five-membered ring at C8 through C12 (see Figure 24-4, inset). The term *prostaglandins* is employed widely but should be used only to describe the oxygenation products that contain the five-membered carbon ring. A family of acidic lipids found first in human seminal fluid, PGs were misnamed because it was thought they were produced in the prostate gland rather than in the seminal vesicles.²⁸⁻³⁰ The alphabetic PG nomenclature (e.g., PGE, PGF, PGD) is related to the chemical architecture of the cyclopentane ring. PGE and PGF differ only in the presence of a ketone or hydroxyl function at C9 (see Figure 24-4). These compounds are made by a variety of cells (e.g., PGE₂ and PGD₂ by isomerases, PGF_{2 α} by a reductase). In

the nomenclature a subscript numeral after the letters indicates the degree of unsaturation in the alkyl and carboxylic acid side chains. The numeral 1 indicates the presence of a double bond at C13-C14 (PGE₁), 2 marks the presence of an additional double bond at C5-C6 (PGE₂), and 3 denotes a third double bond at C17-C18 (PGE₃).

PGs are produced on demand and seem to exert their effects on the cell of origin or nearby structures. They are not stored in cells and are degraded rapidly *in vivo* by 15-hydroxyprostaglandin dehydrogenase (PGDH) during one passage through the lungs. Abundant experimental evidence supports the view that PGs participate in development of the inflammatory response. Administration to rats of a monoclonal antibody to PGE₂ prevents carrageenan-induced pain and inflammation.³¹ PGs are probably better at potentiating the effects of other mediators of inflammation than they are at inducing inflammation directly. PGE compounds and intermediate hydroperoxides of AA increase pain sensitivity to bradykinin and histamine. The effects of PGE are cumulative, depending on concentration and time. Even small amounts of PGs, if allowed to persist at the site of injury, may in time cause pain.

PGE₂ stimulates bone resorption,³² and its 13,14-dihydro derivative is nearly as potent, which is of interest because derivatives of the biologically active PGs are usually assumed to be of no functional significance. Addition of serum to the culture medium stimulates bone resorption, a process that is complement dependent and PG mediated. The mechanism may help explain bone erosion in joints of patients with RA, in which complement is activated, and PGE₂ concentrations are high. The observation that PGE₁ can stimulate bone formation³³ suggests that PGs physiologically participate in coordination of bone formation and resorption. For example, primary idiopathic hypertrophic osteoarthropathy, a familial disorder, is associated with mutations in PDGH and subsequent impairment of PG degradation. These patients have chronically elevated levels of PGE and exhibit digital clubbing and evidence of both increased bone formation and resorption in their phalanges.³⁴ Many effects of IL-1 and TNF on cells are associated with stimulation of PG production and inflammation. Cartilage explants from osteoarthritis patients express COX-2 (but not COX-1) and release 50 times more PGE₂ in culture than cartilage from healthy subjects and 18 times more PGE₂ than normal cartilage stimulated with cytokines plus lipopolysaccharide. Explants from osteoarthritis patients release IL-1 β , whereas normal cartilage does not express mRNA for pro-IL-1 β or release IL-1 β spontaneously. It seems that in osteoarthritis—and probably in RA—upregulation of cartilage IL-1 β and subsequent production of PGE₂ leads to cartilage degradation.^{35,36}

Mast cells, often overlooked as important in inflammatory responses, are seen in large numbers in synovium from patients early in the course of RA.³⁷ PGD₂, the major PG formed by mast cells, also can mediate histamine release from mast cells exposed to anti-IgE antibody. PGJ₂, formed from the dehydration of PGD₂, seems to function as a brake on the inflammatory response. It reduces macrophage activation, reduces nitric oxide production from stimulated cells, and induces apoptosis in tumor cell lines. PGJ₂ is metabolized to 15-deoxy- δ 12,14 PGJ₂ and δ 12 PGJ₂, which are also biologically active.³⁸ It is not clear whether PGA,

formed from loss of water from the cyclopentane ring, has biologic activity. However, *in vitro*, PGA₂ induces apoptosis in HL-60 cells.³⁹

Prostacyclin

Prostacyclin, discovered in 1976,⁴⁰ has been purified, and the cDNA for prostacyclin synthase has been cloned. In addition to a cyclopentane ring, a second ring is formed by an oxygen bridge between carbons 6 and 9. It is generated from PGH₂ by a distinct prostacyclin synthase, a 56-kD member of the cytochrome P-450 superfamily of enzymes found predominantly in endothelial and vascular smooth muscle cells.¹⁵ Production of prostacyclin can be stimulated by thrombin or generated by transfer of PGH₂ from platelets (the endoperoxide steal), contact with activated leukocytes, or stretching of the arterial wall. It is a powerful vasodilator and inhibits platelet aggregation through activation of adenylate cyclase, which leads to an increase in intracellular cAMP. It is metabolized rapidly (half-life in plasma is less than one circulation time) to the more stable, less biologically active 6-keto-PGF_{1 α} . The enzymatic products of its conversion—2,3-dinor-6 keto-PGF_{1 α} and 6,15-di-keto-2,3-dinor PGF_{1 α} —are also chemically stable and have little biologic activity. They are the major metabolites of prostacyclin excreted in urine, in which they can be assayed as indicators of prostacyclin generation.

Prostacyclin generated in the vessel wall has antiplatelet and vasodilator actions, whereas TXA₂ generated by platelets from the same precursors induces platelet aggregation and vasoconstriction. These two eicosanoids represent biologically opposite poles of a mechanism for regulating the interaction between platelets and the vessel wall and of formation of hemostatic plugs and intra-arterial thrombi. Given the central role of platelets in inflammatory reactions, an appropriate prostacyclin-TX balance is important to regulation of inflammation. The balance may be altered in patients with antiphospholipid antibody syndrome; in patients treated with cyclosporine; and in patients treated with NSAIDs, especially patients treated with selective COX-2 inhibitors. Although COX-2 inhibitors reduce recurrence of colorectal adenomas, they increase the risk for cardiovascular events such as myocardial infarction and stroke.⁴¹

Intravascular infusion of prostacyclin also reduces some of the clinical changes associated with pulmonary embolism. The instability of prostacyclin makes it cumbersome to administer therapeutically. Nonetheless, it has been used with limited success to treat peripheral vascular disease including Raynaud's phenomenon. New therapeutic approaches for treatment of pulmonary hypertension including patients with sarcoidosis and systemic sclerosis are prostacyclin analogues such as epoprostenol, beraprost, and iloprost, but these are not free of adverse events due to intravenous administration.^{42,43} Several drugs including angiotensin-converting enzyme inhibitors and statins release endogenous prostacyclin from vascular endothelium *in vivo*, observations that pave the way for development of new anti-inflammatory and cardioprotective agents.⁴⁴ In addition to its vasodilator effects, prostacyclin suppresses endothelial cell proliferation. Prostacyclin analogues might prove useful as adjunct treatment for some cancers.

Thromboxanes

The endoperoxide PGH_2 can be converted into TXs after the action of the enzyme TX synthase, a microsomal 60-kD member of the cytochrome P-450 family, which is quite active in the platelet. The gene that encodes the enzyme has been cloned. TXs contain a six-member oxane ring instead of the cyclopentane ring of the PGs. TX synthase converts PGH_2 into equal amounts of TXA_2 and 12L-hydroxy-5,8,10-heptadecatrienoic acid. TXA_2 stimulates platelet activation, contributes to intravascular aggregation of platelets, and contracts arteriolar and bronchiolar smooth muscles. It is hydrolyzed rapidly (half-life is 30 seconds) to the inactive, stable, measurable product, TXB_2 ; its actions are limited to the microenvironment of its release.

The extraordinary rapidity with which platelets adhere to damaged tissue, aggregate, and release potent biologically active materials suggests that the platelet is well suited to be a cellular trigger for the inflammatory process. Efforts directed at suppression of TX synthesis and platelet aggregation may result in limitation of inflammatory responses, especially in coronary arteries. Inhibition of platelet aggregation may be important to the anti-inflammatory effects of aspirin and other NSAIDs. Long-term administration of low doses of aspirin (40 mg/day—the lowest dose predicted to cause total inhibition of TX formation in serum, according to mathematic modeling)—has inhibitory effects on platelet function *ex vivo* that are indistinguishable from the effects caused by giving 325 mg/day of aspirin.⁴⁵ Aspirin acetylation of COX in platelets occurs in the portal vein where the aspirin concentration is high before it is metabolized in the liver, which explains why the 81-mg dose of aspirin is so effective in prevention of heart attacks and strokes. Platelets lose their ability to aggregate until new platelets are formed in about a week.¹¹ Nonetheless, the response to aspirin can vary among individuals. It has been suggested⁴⁶ that serum TXB_2 levels be monitored to ensure the efficacy of aspirin therapy. Even low-dose aspirin has some depressive effect on prostacyclin synthesis, however. This means recovery of vascular prostacyclin production may be more difficult to attain in elderly patients.⁴⁷

Selective inhibition of TX synthase represents an approach that may be used to suppress TXA_2 synthesis without depressing prostacyclin formation. The endoperoxide steal seems to function *in vivo* after administration of a TX synthase inhibitor. Antagonists of the receptors shared by endoperoxide and TXA_2 have been developed, and these agents inhibit platelet aggregation in patients who are recalcitrant to TX synthase inhibition. Novel agents targeting TX receptors and TX synthase have improved treatment of vasculitis and cardiovascular and renal diseases.⁴⁸ More specific inhibition of TX action may become possible now that TX receptors have been cloned and characterized.⁴⁹

Lipoxygenase Pathways

In contrast to the COX pathway, in which stable products have three atoms of oxygen covalently attached to AA from 2 moles of molecular oxygen, lipoxygenases insert a single oxygen atom into the molecular structure of AA. Separate

lipoxygenases exist in certain cells and have strict structural requirements for their substrates. Three Six major mammalian lipoxygenases insert their oxygen atoms into the 5, 12, or 15 position of AA, with formation of a new double bond and hydroperoxy group. The hydroperoxy fatty acids (hydroxyperoxy-eicosatetraenoic acid [HPETE]) can be reduced by peroxidases in the cell to yield the corresponding hydroxy fatty acids (hydroxy-eicosatetraenoic acid [HETE]). The exclusive lipoxygenase product of the human platelet is 12-HPETE, which on reduction of the hydroperoxy group yields 12-HETE. In contrast, the human neutrophil makes predominantly 5-HPETE, but when high concentrations of AA are added, 15-lipoxygenase can be shown. Lipoxygenases that act on AA are found in the cytosol fraction of cells.

The human 5-lipoxygenase (5-LO) gene has been isolated and characterized^{50,51} and produces a 78-kD enzyme. In myeloid cells the 5-lipoxygenase pathway leads to formation of the biologically active LTs (Figure 24-5) that were originally found in leukocytes and that contain three conjugated double bonds (trienes). Cell activation leads to translocation of 5-lipoxygenase from cytosol to the nuclear membrane, where it encounters the 18-kD, 5-lipoxygenase-activating protein (FLAP). AA is also translocated to 5-lipoxygenase-activating protein FLAP for presentation to 5-lipoxygenase (5-LO). In addition, upon cell stimulation, cPLA₂ is activated and also associates with the nuclear membrane, close to FLAP. The ability of macrophages and dendritic cells to respond appropriately during innate immune responses is likely regulated by 5-LO and 12-LO.^{52,53} The unstable HPETE is the initial metabolite of each lipoxygenase pathway. HPETE is reduced to the more stable HETE or is converted by 5-LO to LTA_4 . LTA_4 can be converted to LTB_4 (in neutrophils and macrophages) or conjugated with reduced glutathione to form LTC_4 (in eosinophils, mast cells, endothelial cells, and macrophages). In contrast to lipoxygenase, which is mainly distributed in myeloid cells, LTA_4 hydrolase (5,12-dihydroxy-eicosatetraenoic acid), a zinc-requiring enzyme that converts LTA_4 to LTB_4 , is widely distributed. From the cDNA sequence, it was suggested that mRNA for LTA_4 may have a short half-life, which could account for the properties of extremely rapid production and shutdown of LTB_4 and other eicosanoid biosynthesis.

LTA_4 can be exported from the cell of origin and converted in other cells by LTA_4 hydrolase to LTB_4 . This variation on the endoperoxide steal—perhaps better called *transcellular metabolism*—also applies to conversion of LTA_4 to LTC_4 by LTC_4 synthase, a glutathione-S-transferase.⁵⁴ Although human endothelial cells do not produce terminal products of the 5-lipoxygenase system, they do generate LTC_4 from LTA_4 provided by neutrophils. LTC_4 and its products, LTD_4 and LTE_4 , constitute the biologic mixture previously known as slow-reacting substance of anaphylaxis. LTD_4 and LTE_4 arise from LTC_4 after sequential removal of γ -glutamic acid and glycine from LTC_4 . The enzyme γ -glutamyl transpeptidase is present in many cells as part of a complex enzymatic system involved in glutathione biosynthesis and amino acid transport. In many systems the major sulfidopeptide LT has been reported to be LTD_4 , rather than the precursor LTC_4 . Removal of glycine from LTD_4 results in LTE_4 with concomitant loss of a significant

Figure 24-5 5-Lipoxygenase pathway of arachidonic acid metabolism. HETE, hydroxy-eicosatetraenoic acid; HPETE, hydroperoxy-eicosatetraenoic acid; LT, leukotriene.

amount of biologic activity. The principal route of inactivation of LTB₄ is by omega oxidation.

Products of the Lipoxygenase Pathways

The biologic effects of compounds produced in the lipoxygenase pathway indicate their importance in inflammatory diseases.⁵⁵ They are the major mediators of inflammation formed by the oxygenation of AA and are implicated as key mediators in several diseases including inflammatory bowel disease, psoriasis, bronchial asthma, and RA.

5-HETE and 5-HPETE stimulate the generation of superoxide in human neutrophils. These compounds also augment intracellular calcium levels, facilitating PKC-dependent activation of a superoxide generating system of neutrophils. LTB₄ increases adherence of leukocytes to

endothelial cells, a response that is augmented by exposure of the endothelial cells to TNF. LTB₄ does not seem to have a direct vascular contractile action because it is inactive in the hamster cheek pouch preparation and several other microvasculature systems. In rabbit skin, administration of LTB₄ with a vasodilator PG induces plasma exudation, which suggests that LTB₄ may assist enhanced vascular permeability. Increased venule permeability does occur in response to LTC₄, LTD₄, and LTE₄. LTB₄ is a potent chemotactic factor for neutrophils and is weakly chemotactic for eosinophils. LTB₄ and, to a lesser extent, 5-HETE enhance migration of T lymphocytes in vitro. Synovial cells produce 5-HETE but do not seem to produce significant amounts of LTB₄. However, macrophages that invade the synovium in RA patients generate substantial quantities of 5-lipoxygenation and 15-lipoxygenation products including

LTB₄. In addition to the local signs of inflammation induced by products of the lipoxygenase pathway, these compounds may contribute to the pain, tenderness, and aching common in RA patients. LTB₄ also seems to serve an immunoregulatory function. It stimulates differentiation of competent CD8⁺ T lymphocytes from precursors lacking the CD8 marker. LTB₄ also stimulates interferon- γ and IL-2 production by T cells and biosynthesis of IL-1 by monocytes.⁵⁶

Synovial cell proliferation and endothelial cell proliferation are central to propagation of the rheumatoid joint lesion. LTB₄ and the cysteinyl LTs act as growth or differentiation factors for several cell types in vitro. These compounds also increase proliferation of fibroblasts when PG synthesis is inhibited,⁵⁷ findings that emphasize the importance of interactions between the COX and lipoxygenase pathways and suggest limitations to NSAID therapy for RA patients.

Strategies for inhibiting production or antagonizing the actions of LTs include development of selective LT receptor antagonists and inhibition of the production of LT by blocking the action of 5-lipoxygenase. Inhibition of enzymes distal in the LT cascade such as LTA₄ hydrolase⁵⁸ is also a promising strategy for development of anti-inflammatory drugs. A compound that inhibits binding of 5-lipoxygenase to 5-lipoxygenase-activating protein exhibits anti-inflammatory effects in animal models. Lipoxygenase inhibitors have not been useful for treatment of RA patients. New compounds, mainly resulting from natural products chemistry, seem more promising.⁵⁹ In addition, the existing agents may be aiming at the wrong target. Fibroblasts such as synovial cells do not make much LTB₄, but they do make 12-HETE, which is a growth factor, through a cytochrome P-450 pathway.⁶⁰ Cytochrome P-450 inhibitors may be more to the therapeutic point. Some inhibitors are more effective when activated by exposure to light.⁶¹ These inhibitors might prove useful as topical agents for treatment of inflammatory skin disease.

Lipoxygenase activities do not lead solely to production of mediators of inflammation. DGLA is converted by 15-lipoxygenase into 15-HETE, which is incorporated into DAG and exerts anti-inflammatory effects partly by interfering with PKC- β activity. A lipoxygenase product of linoleic acid, 13-hydroxyoctadecadienoic acid, also suppresses inflammation and cell proliferation by means of a similar mechanism.⁶² EPA is converted by lipoxygenase into 15-hydroxyeicosapentaenoic acid, which also exhibits anti-inflammatory properties.⁶³

Lipoxins

Another large family of AA metabolites arises from the sequential action of 5-lipoxygenases and 15-lipoxygenases. Addition of 15-HPETE and 15-HETE to human leukocytes results in formation of a pair of oxygenated products containing a unique conjugated tetraene. One compound (lipoxin A₄ [LXA₄]) was identified as 5,6,15L-trihydroxy-7,9,11,13-eicosatetraenoic acid, and the other proved to be its positional isomer (lipoxin B₄ [LXB₄]), 5D-14,15-trihydroxy-6,8,10,12-eicosatetraenoic acid (Figure 24-6). Because both of these compounds can arise through an interaction between lipoxygenase pathways, the trivial name lipoxins (i.e., lipoxygenase interaction products) was

Figure 24-6 Lipoxin biosynthesis. The lipoxins result from the sequential action of 15-lipoxygenase and 5-lipoxygenase on arachidonic acid.

introduced. Platelet 12-lipoxygenase can transform neutrophil LTA₄ to lipoxins. The complete stereochemistry and multiple routes of biosynthesis for the biologically active LXA₄ and LXB₄ have been determined.⁶⁴

That macrophages of rainbow trout generate lipoxins rather than LTs or PGs as their major products of AA metabolism indicates that lipoxins have a long evolutionary history. LTs and lipoxins can be generated in parallel in fish. In humans, the process has diverged to a two-cell system. Biosynthesis of eicosanoids by transcellular and cell-cell interactions is recognized as an important way to generate and amplify lipid-derived mediators. Lipoxins can be generated within the vascular lumen during platelet-leukocyte interactions and at mucosal surfaces via leukocyte-epithelial cell interactions. In humans, lipoxins are formed in vivo during multicellular responses such as inflammation, atherosclerosis, and in asthma. These tetraene-containing

products serve as stop signals in that they prevent leukocyte-mediated tissue injury. Acute inflammation is a primitive protective response,⁶⁵ and chronic inflammation involves failure of mechanisms designed to stop the acute response. A major problem in joints of patients with RA, as well as of patients with other conditions associated with chronic inflammation and tissue injury, is that inflammation often does not resolve. Lipoxins and aspirin-induced 15-epilipoxins are endogenous components of events governing resolution of inflammation. Aspirin acetylation of COX-2 in endothelial cells suppresses PG synthesis but leads to generation of 15R-HETE from AA, which is transformed to 15-epilipoxin by leukocytes in a transcellular biosynthetic route involving vascular endothelial cells or epithelial cells. These 15-epilipoxins exhibit anti-inflammatory and antiproliferative actions in vitro and in vivo. Stable analogues of LXA₄ and of aspirin-triggered lipoxin (ATL) also suppress inflammation in animal models. In addition, acting as antagonists at the receptor CysLT1, ATL analogues counteract the inflammatory actions of cysteinyl leukotrienes.⁶⁶ These observations may lead to the development of new anti-inflammatory drugs. For example, induction by interferon of particular genes is important to the pathogenesis of systemic lupus erythematosus. A stable synthetic analogue of LXA₄ suppresses several interferon-induced genes and reduces kidney damage in a murine model of immune-mediated nephritis.⁶⁷

Lipoxins block human polymorphonuclear leukocyte chemotaxis but stimulate monocyte chemotaxis and adherence. Monocytes do not release mediators of inflammation in response to lipoxins, however, and lipoxins are converted rapidly by monocytes to inactive compounds. This selective effect on chemotaxis suggests that lipoxins can play a role in wound healing. LXA₄ antagonizes LTD₄-induced vasoconstriction in vivo and blocks binding of LTD₄ to its receptors on mesangial cells. LXA₄ suppresses LTB₄-induced plasma leakage and leukocyte migration and blocks LTB₄-induced neutrophil inositol triphosphate generation and calcium mobilization, but not superoxide anion generation. Conversely, LXA₄ activates PKC and is more potent in this regard than DAG and AA. LXA₄ seems to be specific for the γ subspecies of PKC. These results indicate that lipoxins may regulate the actions of vasoconstrictor LTs and suggest that LXA₄ may be an important modulator of intracellular signal transduction.

It was long thought that resolution of inflammation was a passive process. Contrary to this belief, the inflammatory response does not dissipate but is mediated actively by products of COX and LO and acetylation of these enzymes.⁶⁸ Discovery that omega-6 and omega-3 polyunsaturated fatty acids are also substrates for enzymatic oxygenation reactions that produce lipid mediators with potent anti-inflammatory and proresolution actions has advanced our understanding of the inflammatory response. In addition to lipoxins, entire spectra of specialized proresolving mediators (SPM) have been uncovered. These include resolvins, protectins, and maresins.⁶⁹ Like the lipoxins, resolvins are formed via specific transcellular biosynthetic pathways from both n-6 and n-3 fatty acids. EPA-derived (E series) cellular interaction products formed in resolving exudates have been termed resolvins (RvE1 and E2). The omega 3 docosahexaenoic acid (DHA) can be catalyzed via the 15-LO pathway to

dihydroxy products (D series resolvins D1-D5), which also stimulate resolution of inflammation and enhance innate host defense mechanisms. Lipoxins and resolvins act as endogenous receptor agonists at low concentrations (pM to nM) and at specific G protein-coupled membrane spanning receptors to actively downregulate inflammatory events and to stimulate resolution of an inflammatory exudate. A single cell type can also form oxygenated lipid mediators with counterregulatory actions. DHA can also be catalyzed via the 15-LO pathway to a dihydroxy product termed *protectin D1* (PD1), which can protect against tissue damage and activate resolution of inflammation. In a second single oxygenation route, a lipid mediator termed *maresin* (macrophage mediators in resolving inflammation) is formed via the action of human 12-LO. The maresin biosynthetic pathway is activated in macrophages during phagocytosis. Maresin 1 (MaR1) reduces neutrophil migration and increases macrophage phagocytosis of apoptotic cells, thereby exhibiting the hallmarks of SPM. An animal model that has been developed more closely resembles a chronic inflammatory response and allows measurement of the extent and pace of the response including resolution and its sensitivity to anti-inflammatory and proresolving therapies.⁷⁰

Isоеicosanoids

Isоеicosanoids, isomers of enzymatically derived eicosanoids, are derived from the free radical-mediated peroxidation auto-oxidation of polyunsaturated fatty acids including omega-3 fatty acids.⁷¹ They include members of the F, D, and E isoprostanes, isothromboxanes, and isoleukotrienes. Analysis of the isoprostanes (IsoP) indicates that they reflect lipid peroxidation in vivo. Theoretically, 64 F-type isoprostanes may be formed, although few have been characterized. As more isoprostanes are identified, the nomenclature probably will continue to change. One F-type isoprostane, isoprostane F_{2 α} III (formerly 8-isoprostaglandin F_{2 α}) has been studied in detail because of its biologic activity in vitro. Isoprostane F_{2 α} III (Figure 24-7) is a potent vasoconstrictor and may function as a mitogen, with actions that are blocked by TX receptor antagonists. Although isoprostanes may act as ligands at TX or PG receptors (8,12-isoprostane F_{2 α} III activates the PGF_{2 α} receptor), they may also activate specific isoprostane receptors.

Isoprostanes

What all isoprostanes have in common, and what distinguishes them from the PGs, is the fact that the top (α) and the bottom (ω) side chains are always syn—that is, crowded together on the same face of the cyclopentane ring. The minimal requirement for generation of an isoprostane is a polyunsaturated fatty acid with three contiguous methylene-interrupted double bonds, a requirement met by dozens of naturally occurring polyunsaturated fatty acids. Brain tissue contains particularly high levels of fatty acids formed from docosahexaenoic acid (DHA; C22:6n3). By the same peroxidation process undergone by AA, DHA in nerve cell membranes is converted to several neuroprostanes (NeuroP). Of these, F4-NeuroP is a promising biomarker for several neurodegenerative diseases. A similar mechanism in plants

Figure 24-7 Isoprostane $F_{2\alpha}$ structures. Jagged lines indicate that stereochemistry is uncertain.

yields phytoprostanes (PhytoP) from α -linolenic acid. In contrast to conventional, enzymatically derived PGs that are formed intracellularly and released immediately, isoprostanes are formed in the cell membrane, cleaved by phospholipases, circulate in plasma, and are excreted in urine. As stable end products of lipid peroxidation, endogenously formed IsoP are useful markers of oxidative stress and independent risk markers for coronary artery disease. They are increased in several diseases including acute respiratory distress syndrome, in which polymorphonuclear leukocytes generate reactive oxygen species that damage pulmonary epithelium. The immune cells in inflamed tissues are exposed to reactive oxygen intermediates produced by neutrophils and other phagocytic cells. Oxidants are also generated as mediators in intracellular signaling pathways by cytokines such as IL-1 β and TNF. Isoprostanes are likely to be proved to be important in inflammatory conditions such as vasculitis and RA. Because isoprostanes are released preformed, their production is not blocked by NSAIDs, which suppress metabolism of free AA. It is possible that inflammation unresponsive to NSAIDs may yield to inhibition of isoprostanes. In keeping with the notion of eicosanoids as regulators, however, some isoprostanes suppress release of mediators of inflammation from macrophages, and a PhytoP (E1-PhytoP) signals through PPAR γ and NF κ B to suppress IL-12 production by activated dendritic cells and reduce cytokine production by Th1 and Th2 cells.^{72,73}

Endocannabinoids

Groups of naturally occurring members of the eicosanoid superfamily that can activate cannabinoid receptors and are derivatives of long-chain fatty acids have been referred to as *endocannabinoids*. They are not stored in cells. Rather, they are synthesized rapidly in the manner of PGs and LTs from lipid precursors and are released from—among other cells—cells of the immune system during immune/inflammatory responses. They can then activate cannabinoid receptors on the same or adjacent cells and are metabolized rapidly by the specific serine hydrolase, fatty acid amide hydrolase (FAAH), or by monoglyceride lipase or *N*-acylethanolamine. Thus inhibition of FAAH offers a strategy for treatment of chronic inflammatory pain.⁷⁴ One of the most important endocannabinoids is anandamide (from the Sanskrit word for “bliss”), the amide conjugate of

AA and ethanolamine (arachidonoyl ethanolamide) (Figure 24-8). Anandamide is not stored in cells. Rather, it is synthesized rapidly in response to stimuli in the manner of PGs and LTs. Anandamides and other endocannabinoids such as 2-arachidonylglycerol and virodamine are involved in a wide range of regulatory functions including pain perception and modulation of immune responses, actions mediated via cannabinoid 1 (CB1) and CB2 receptor subtypes resulting in activation of G proteins of the G(i/o) family. Of particular relevance to joint tissue injury is the capacity of anandamide to suppress TNF-induced NF κ B activation by direct inhibition of I- κ B kinase, an action that is independent of CB1 or CB2 activation.

Acid congeners of anandamides are lipoamino acids (elmiric acids) that exist as endogenous substances, regulate tissue levels of anandamide, and exhibit anti-inflammatory effects and the capacity to assist resolution of inflammation. One such compound, *N*-arachidonylglycine (NAGly), is found in many tissues at higher concentrations than anandamide. It has analgesic actions similar to those reported for anandamide but does not exhibit psychotropic action. The polyunsaturated amides dihomogammalinolenoyl (20:3n6) and adrenoyl (22:4 n6) ethanolamide are found in mammalian brain. It is likely that n-3 fatty acid ethanolamides also exist in mammalian tissues. A library of elmiric acids (n-3 and n-6) has been synthesized. Several of these compounds exhibit anti-inflammatory activity, likely in part by increasing production of PG $_2$ and also seem to modulate immune responses.⁷⁵⁻⁷⁷ Discovery of naturally occurring and synthetic analogues and metabolites of anandamide suggest that a family of such biologically active substances exists. The polyunsaturated amides dihomogammalinolenoyl (20:3 n-6) and adrenoyl (22:4 n-6) ethanolamides have been found in mammalian brain.⁷⁸ It is likely that n-3 fatty acid ethanolamides also exist in mammalian tissues. That anandamide can enhance its own synthesis in macrophages suggests the presence of a rapid response to counter excessive inflammatory or immune responses. Anandamide is

Figure 24-8 Chemical structure of anandamide (arachidonoyl ethanolamide).

converted by COX-2 (but not by COX-1) into PGE₂ or PGF_{2α} ethanolamide directly, without going through free AA.⁷⁸ These novel PGs (“prostamides”) are pharmacologically active.⁷⁹ Because anandamide is a substrate for COX-2, inhibitors of COX-2 may reduce anandamide metabolism with a subsequent increase in concentration of the anandamide. A combination of anandamide with ibuprofen produces synergistic analgesia in rats.⁸⁰ In addition, anandamide is metabolized by fatty acid amide hydrolase. Compounds that inhibit fatty acid amide hydrolase and maintain anandamide levels may be useful anti-inflammatory agents. A naturally occurring lipoamino acid, *N*-arachidonylglycine (NAGly), is also a substrate for COX-2, giving rise to amino acid conjugates of the PGs.⁸¹

EICOSANOID RECEPTORS

For many years, it was thought that the lipophilic eicosanoids—in contrast to the peptide molecules for which receptors were characterized routinely—simply “diffused” into cell membranes or were carried in by a binding protein. The isolation and cloning of eicosanoid receptors changed that thinking.⁸²

Prostaglandin Receptors

PGs exert most of their actions through G protein–coupled receptors (GPCRs). They also bind to peroxisome proliferator-activated receptors (PPARs) *in vitro*, but it is not clear that PPARs mediate PG effects *in vivo*. Receptors for the COX products are designated P receptors, depending on the prostanoid that has most affinity for them. These receptors include the PGD receptors (DP); four subtypes of the PGE receptor (EP1 through EP4); the PGF receptor (FP); the PGI₂ receptor (IP); and the TX receptor (TP). The IP, DP, EP2, and EP4 receptors mediate increases in cellular cAMP, whereas TP, FP, and EP1 receptors induce calcium mobilization. EP2, EP4, and IP regulate macrophage cytokine production in a similar manner. As might be expected, signaling through these receptors is more complicated. Studies designed to understand PGE₂ signaling suggest involvement of PI3 kinase, mitogen-activated protein kinase (MAPK), and Wnt pathways in EP2R/EP4R regulation of cell growth, migration, and apoptosis.³⁴ PGE₂ is the most abundant of the major eicosanoids in the joint space of patients with RA. It is therefore of interest that oral administration of a selective antagonist of EP4 inhibits joint inflammation in the rat adjuvant arthritis model and relieves pain in a guinea pig model of osteoarthritis, whereas EP1 and EP3 antagonists do not have anti-inflammatory or analgesic actions in these animal models.⁸³ Although PGI₂ analogues are ligands for IP and increase cAMP, high concentrations of PGI₂ analogues activate phospholipase C and induce calcium mobilization. Identification of a second PGD receptor (DP2) and the limited inhibition of its inflammatory effects by DP1 receptor antagonists has stimulated development of selective DP2 antagonists for the treatment of asthma in which allergen challenge induces PGD₂ production with subsequent airway tissue contraction and inflammation.⁸⁴

Modification of immune cell and surrounding cell functions by prostanoids during immune or inflammatory

responses is influenced by the different repertoire of PG receptors expressed on these cells. Knowledge of the roles of the P receptors in physiologic and pathologic processes has been advanced by experiments with mice deficient in the receptors (knockout mice). Mice deficient in each EP receptor subtype have been generated, and highly selective agonists for these receptors have been developed. As noted previously,³⁴ PGE can suppress or induce bone formation. EP2 and EP4 knockout mice exhibit impaired osteoclastogenesis and inflammation-induced bone resorption. The receptor mediating PGE-induced bone formation is unknown, although it has been proposed that EP2R and EP4R mediate the anabolic effects of PGE₂ on bone. In animal models, acute inflammation and pain are completely absent in IP-deficient mice. The profile of PG formation changes as the inflammatory response evolves to a more chronic state, so other receptors are probably involved. It is unlikely that blockade of one receptor would completely block an inflammatory response. More encouraging is the fact that PGs participate in allodynia, a pain response to a usually nonpainful stimulus. Knowing the contribution of P receptors to allodynia might lead to better treatment of neuropathic pain and myofascial pain syndromes such as fibromyalgia.

Stimulation of thromboxane/endoperoxide receptors (TP) elicits platelet aggregation and contraction of vascular smooth muscle and promotes expression of adhesion molecules with subsequent movement of monocytes/macrophages from the circulation to tissue. Thus TP antagonists reduce vascular inflammation, are antithrombotic, and maintain vasodilation, actions that mark them as potential agents for treatment of cardiovascular disorders and other conditions characterized by chronic inflammation.⁸⁵

The availability of cloned P receptors should assist development of more effective receptor-active compounds. The PGI₂ analogue iloprost is useful for treatment of peripheral vascular disease and pulmonary hypertension. Although iloprost binds to IP with high affinity, it also binds EP1 and EP3. It may be that targeting activation, blockade, or both of a single P receptor or a specific set of P receptors would provide advantages over compounds that work “upstream” such as the COX-2 inhibitors or traditional NSAIDs. For example, it is clear that E prostaglandins are the most important of the endogenous eicosanoids for modulation of the function and mucosal integrity of the gastrointestinal tract. Protection by PGE₂ against acid reflux esophagitis and against ethanol- and indomethacin-induced gastric mucosa injury is mimicked by EP1 agonists and attenuated by an EP1 antagonist, whereas EP4 antagonism does not affect the integrity of gastrointestinal mucosa. In addition, PGE₂ does not exhibit gastric cytoprotection in EP1 knockout mice. In the small intestine the protective effect of PGE₂ on indomethacin-induced damage is mimicked by both EP3 and EP4 agonists.

Further evidence of the importance of eicosanoids in immune cell function and regulation of immune responses derives from experiments with mice deficient in PG receptors, which indicate that PGE₂ assists and amplifies IL-12-mediated T helper 1 (Th1) cell differentiation and IL-23-mediated Th17 cell expansion. These PGE₂ actions and those of PGD₂ and PGI₂—also discovered using

receptor-deficient mice—contribute to development of immune diseases.⁸⁶ Mice lacking the $\text{PGF}_{2\alpha}$ receptor are protected against bleomycin-induced pulmonary fibrosis,⁸⁷ a finding with implications for treatment of systemic sclerosis.

The implications for therapy derived from this new knowledge are clear and exciting, but prostanoid analogues with selective binding properties need to be developed. Some progress has been made, and it seems that deletion of P receptors, with the exception of EP4, is not associated with serious problems of fetal development or physiologic function in animals.

Leukotriene Receptors

Less is known about the surface receptors for LTs. Surface receptors for LTB_4 , denoted BLT1 and BLT2 (LTB_4 R-1 and LTB_4 R-2), and for the cysteinyl LTs also exert their actions through transmembrane spanning GPCRs.^{88,89} High-affinity LTB_4 receptors transduce chemotaxis and adhesion responses, whereas low-affinity receptors are responsible for secretion of granule contents and superoxide generation. The BLT1 receptor has been cloned and characterized as a 43-kD GPCR with seven transmembrane spanning domains, is expressed in inflammatory cells, and has a high degree of specificity for LTB_4 , with a K_d of 0.15 to 1 nM. BLT2 is homologous to BLT1 but has lower affinity for LTB_4 (K_d 23 nM) and a different specificity and binding profile for BLT antagonists. BLT2 knockout mice express normal levels of BLT1 but are protected from development of disease in the K/BxN model of inflammatory arthritis.⁹⁰ The COX-1-derived ligand 12(S)-hydroxyheptadeca-5Z,8E,10E-trienoic acid (12-HHT), produced during thromboxane synthesis, is an endogenous high-affinity ligand for BLT2 (now called BLT2/HHTR), another example of a connection between the LO and COX pathways. LTB_4 in particular among the LTs is involved in development of atherosclerosis, which has emerged as a major concern for patients with inflammatory arthritis and lupus. The receptor for cysteinyl LTs includes two subtypes—Lys LT_1 and Cys LT_2 —that have been identified pharmacologically, although their molecular structures are unknown. The cysteinyl-LTs are recognized by at least two GPCRs denoted CysLT₁ and CysLT₂. CysLT₁ contains 336 amino acid residues, and the gene encoding the receptor is located on the X chromosome. CysLT₂ contains 345 amino acids with 40% sequence identity to CysLT₁. CysLT₁ mediates calcium mobilization and inhibition of adenylate cyclase, whereas CysLT₂ mediates calcium mobilization and increased cAMP concentrations. The preferred ligands for CysLT₁ are $\text{LTD}_4 > \text{LTC}_4 > \text{LTE}_4$. CysLT₂ binds LTC_4 and LTD_4 equally, whereas LTE_4 exhibits low affinity for the receptor. Both receptors have wide tissue and cellular distribution including a presence in cells which participate in immune responses.³ Most actions of the cysteinyl LTs are mediated by CysLT₁. More than a dozen chemically distinct, specific, and selective antagonist drugs that block the binding of LT to CysLT₁ have been identified. Clinical use of these compounds has mainly been in the treatment of asthma. A 5-lipoxygenase-specific inhibitor reduced whole-blood LTB_4 production but did not suppress synovitis in a 4-week trial of RA patients.⁹¹ A challenge in designing “antireceptor therapy” is the genetic variation in

GPCRs that can be associated with disease.⁹² Adding to the complexity is the fact that variants may result in altered predisposition to disease, rather than manifestation of the disease. Each variant provides an opportunity to understand receptor function such as recycling or desensitization, enhancing the potential for development of therapy.

Lipoxin Receptors

Lipoxins can act at their own specific receptors for LXA_4 and LXB_4 , and LXA_4 can interact with a subtype of LTD_4 receptors. Lipoxins can also act at intracellular targets within their cell of origin or after uptake by another cell. The cDNA for the seven-transmembrane-spanning, G protein-coupled LXA_4 receptor named ALX/FPR2 ($K_d \approx 0.7$ nM) has been cloned and characterized. Its signaling involves a novel polyisoprenyl-phosphate pathway that regulates phospholipase D.⁹³ Lipoxin actions are cell type specific. The monocyte and neutrophil LXA_4 receptors are identical at the cDNA level, but they evoke different responses and the LXA_4 receptor on endothelial cells seems to be a structurally distinct form. LXA_4 also binds to the human orphan receptor GPR32, a member of the chemoattractant receptor family. Like LXA_4 , 15-epi- LXA_4 is an anti-inflammatory SPM that binds and activates ALX/FPR2 ($K_d \approx 2$ nM). Lipoxin B₄ (LXB_4) and aspirin-triggered 15-epi LXB_4 also have anti-inflammatory actions by oral administration and topical application. Stereoselective actions of these compounds indicate they have their own yet-to-be-identified receptors. The resolvin RvE1 binds to the GPCR CMKLR1 ($K_d \approx 11$ nM). The functional importance of this interaction is demonstrated by downregulation of IL-12 in murine dendritic cells. RvE1 also exerts partial agonism at the LTB_4 receptor BLT1 ($K_i \approx 70$ nM). Displacement of LTB_4 constitutes a mechanism whereby RvE1 dampens the inflammatory actions of LTB_4 . Experimental evidence has been obtained for the existence of specific receptors for D-series resolvins. The LXA_4 receptor ALX/FPR2 also binds RvD1. Thus two counterregulatory lipid mediators are ligands for the same receptor. The mechanism of that process is not clear.⁶⁹

Nuclear Receptors

Nuclear receptors are a superfamily of ligand-regulated transcription factors that interact with other transcription factors and with co-regulators that either enhance (co-activators) or inhibit (co-repressors) transcription. The major nuclear receptors involved in regulation of inflammation are the glucocorticoid receptors (GRs), peroxisome proliferator activated receptors, liver X receptors (LXRs), and the orphan receptor nuclear receptor related protein (Nurr1). Other members of the nuclear receptor family that contribute to regulation of inflammation include estrogen receptors, vitamin D receptor, and retinoic acid receptors. The clinical efficacy of glucocorticoids is well known, but knowledge of their mechanisms of action has been slow to emerge. The ability of GR to repress inflammatory responses is due in part to interference with other signal-dependent transcription factors and disruption of activator/co-activator complexes. PPARs are members of the nuclear receptor family of transcription factors, a large and diverse group of

proteins that mediate ligand-dependent transcriptional activation and repression. PPARs were first cloned as nuclear receptors that mediate the effects on gene transcription of synthetic compounds called *peroxisome proliferators*. Several mechanisms account for the anti-inflammatory action of PPAR γ including inhibition of NF κ B; inhibition of transcription of genes encoding for chemokines, IL-1 β , IL-12, and MMP-9; and promotion of expression of anti-inflammatory mediators including IL-10 and LXR. LXRs regulate immune synapse formation in dendritic cells and reduce T cell proliferation. Polyunsaturated fatty acids, including γ -linolenic acid (GLA), also act via PPAR γ by stimulating phosphorylation and translocation to the nucleus.⁹⁴ Interest in PPARs increased dramatically when they were shown to be activated by medically relevant compounds including NSAIDs and PGD₂ and its metabolite 15-deoxy- δ 12,14 PGJ₂.⁹⁵ Most information available on a potential role of PPARs in inflammation relates to PPAR γ . Upregulation of PPAR γ reduces expression of several mediators of inflammation, raising the possibility that PPAR γ ligands may be therapeutic for diseases characterized by inflammation. However, the metabolite 15-deoxy- δ 12,14 PGJ₂ also can exhibit anti-inflammatory activity in a PPAR γ -independent manner. PPAR α is expressed mainly in tissues that have a high fatty acid catabolism including liver and the immune system. LTB₄ is an activator and natural ligand of PPAR α .⁹⁶ Activation of PPAR α results in induction of genes involved in fatty acid oxidation pathways that degrade fatty acids and derivatives including LTB₄. Thus a feedback mechanism that controls inflammation is established. Mechanisms for the anti-inflammatory actions of PPAR β/δ include induction of an anti-inflammatory co-repressor protein, inhibition of NF κ B, and induction of anti-inflammatory mediators. Experiments with PPAR knockout mice indicate that PPAR α suppresses LTB₄-induced inflammation. PPARs are being considered as therapeutic targets for a wide range of immune-mediated diseases characterized by chronic inflammation.⁹⁷ Overexpression of Nurr receptors reduces inflammatory cytokine expression, and mutations in the Nurr 1 gene are associated with diminished counterregulation of inflammation.⁹⁸

Several kinases that facilitate co-repressor turnover have been identified. These kinases represent important pharmacologic targets because their inhibition should block gene expression of inflammatory mediators while bypassing the clinically significant adverse events associated with direct targeting of the nuclear receptors. A small molecule inhibitor of c-Jun terminal kinase is effective treatment in animal models of arthritis.⁹⁸

PLATELET-ACTIVATING FACTOR

Platelet-activating factor (PAF, 1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholine) is a potent mediator of inflammation that causes neutrophil activation, increased vascular permeability, vasodilation, and bronchoconstriction in addition to platelet activation. PAF is formed by a smaller number of cell types than the eicosanoids, mainly leukocytes, platelets, and endothelial cells. Because of the extensive distribution of these cells, however, the actions of PAF can manifest in virtually every organ system. In contrast to the two long-chain acyl groups present in

Figure 24-9 Chemical structure of platelet-activating factor.

phosphatidylcholine, PAF contains a long-chain alkyl group joined to the glycerol backbone in an ether linkage at position 1 and an acetyl group at position 2 (Figure 24-9). PAF represents a family of phospholipids (PAF-like lipids: PAF-LL) because the alkyl group at position 1 can vary in length from 12 to 18 carbons. PAF, similar to the eicosanoids, is not stored in cells. Rather, it is synthesized when cells are stimulated, at which time the composition of the alkyl group may change. The immediate effects of PAF are mediated through a cell surface GPCR, PAFR. PAFR is coupled to Gi, Gq, and G12/13. Activation of PAFR results in inhibition of cyclic AMP, mobilization of calcium, and activation of mitogen-activated protein kinases, whereas long-term responses depend on intracellular—probably nuclear—receptor activation.⁹⁹

Despite the potent inflammatory effects of PAF, its inhibition in animal models does not lead to marked suppression of inflammatory responses. The synthesis of PAF is tightly regulated, and a family of intracellular and extracellular phospholipases A₂ (PAF acetylhydrolases [PAF AHs]) degrade PAF and PAF-LL, thereby regulating their half-life and their engagement with the PAFR. In addition, receptor desensitization controls binding of PAF to its receptor. Plasma PAF Ah derives from macrophages, dendritic cells, and platelets during an inflammatory response and can serve as a circulating marker of inflammation and of atherosclerosis. Mast cells also produce PAF during immediate hypersensitivity reactions, and PAF Ah reduces mortality in murine models of anaphylaxis. Plasma PAF acetylhydrolase, an enzyme that hydrolyzes PAF, may be a particularly important terminator of PAF-induced tissue injury and may find a place among strategies designed to suppress inflammation.¹⁰⁰ Strategies to interrupt cellular activation mediated by dysregulation of PAF signaling include competitive blockade of the PAFR with receptor antagonists and use of recombinant PAF Ah to hydrolyze PAF and PAF-LL upstream from receptor occupancy.¹⁰¹ In addition, PAF production is suppressed by adenosine,¹⁰² which may account for some of the therapeutic efficacy of methotrexate. Given the involvement of PAF in immediate hypersensitivity reactions and inflammation, further search for PAF antagonists is warranted.

EICOSANOIDS AS REGULATORS OF INFLAMMATION AND IMMUNE RESPONSES

The role of PGs in the inflammatory process is not as well defined as previously supposed because in addition to their well-known actions as mediators of inflammation, the stable

PGs PGE and PGI₂ have anti-inflammatory, inflammatory, and immunomodulatory actions.^{103,104} As noted,⁶⁹ PGJ, lipoxins, and an array of eicosanoids seem to act as brakes to protect against runaway inflammatory responses. Even LTB₄ is capable of modulating inflammation and immune responses.⁵⁶ The observations that PGE₁ inhibits platelet aggregation and that it suppresses acute and chronic inflammation and joint tissue injury in animal models¹⁰⁵ led to the notion that COX products of AA metabolism might have anti-inflammatory activity. As it became more clear that NSAIDs have anti-inflammatory effects other than interference with COX production and subsequent PG inhibition,¹⁰⁶ consideration was given to the potential protective effects of PGs.

PGE₁ has remained an orphan among the eicosanoids, mainly because of a long-held notion that not enough of it is made by human cells to be of use and that its biologic effects are no different from the effects of PGE₂ and PGI₂. Contrary to popular belief, PGE₁ is found in physiologically important amounts in humans. Lost in the vast literature on the “AA cascade” are the early observations of Bygdeman and Samuelsson,¹⁰⁷ who found (using bioassay) the concentration of PGE₁ in human seminal plasma (16 µg/mL) to be higher than PGE₂ (13 µg/mL), PGE₃ (3 µg/mL), PGF_{1α} (2 µg/mL), and PGF_{2α} (12 µg/mL). Karim and colleagues¹⁰⁸ found PGE₁ to be the sole PGE in the human thymus. PG immunoassays usually do not distinguish between PGE₁ and PGE₂. To identify PGE₁, it must first be separated from PGE₂ by thin-layer or high-performance liquid chromatography. When such methods have been used, PGE₁ has been identified consistently in platelets, leukocytes, macrophages, vas deferens, oviducts, uterus, heart, and skin.¹⁰⁹ Evidence from in vitro and in vivo experiments indicates that PGs, notably PGE compounds, can suppress diverse effector systems of inflammation. PGE can enhance and diminish cellular and humoral immune responses, observations that reinforce a view of these compounds as regulators of cell function. These actions of eicosanoids depend on the stimulus to inflammation, the predominant eicosanoid produced at a particular time in the host response, and the profile of eicosanoid-receptor expression.^{110,111}

It is now clear that the 2 series prostaglandins (E2, D2, I2) also regulate T cell function and immune responses. PGE₂ reduces production of several inflammatory cytokines including TNF, IFN-γ, and IL-12 and reduces IFN-α production by plasmacytoid dendritic cells (PDCs) from patients with systemic lupus erythematosus (SLE). PGE₂-treated PDCs from SLE patients also induce CD4⁺ T cell proliferation and skew cytokine production toward a Th2 profile.¹¹² Another example of an endogenous link between the COX and LO pathways is provided by the observation that PGE₂ preserves resolution of inflammation in the murine collagen-induced arthritis model by increasing production of the proresolving lipoxin A4.¹¹³

MODULATION OF ECOSANOID SYNTHESIS BY ADMINISTRATION OF PRECURSOR FATTY ACIDS

The relationship between essential fatty acids and PGs was discovered simultaneously and independently by van Dorp

and colleagues¹¹⁴ and Bergstrom and colleagues.¹¹⁵ Both groups reported that AA was converted to PGE₂, and shortly thereafter they showed that PGE₁ is formed from DGLA.¹¹⁶ Attempts to modulate eicosanoid production have been directed at providing fatty acids other than AA as substrates for oxygenation enzymes in an effort to generate a unique eicosanoid profile with immunosuppressive and anti-inflammatory effects.^{63,117} The fatty acids themselves, by virtue of their incorporation into signal-transduction elements, also have effects that are independent of eicosanoid effects on cells involved in inflammation and immune responses.¹¹⁸

Experiments directed at suppression of TX synthesis, enhancement of prostacyclin production, and inhibition of platelet aggregation have been done in an effort to limit inflammatory responses. EPA is not found in appreciable amounts in cells from individuals who eat a Western-style diet. Fish oil lipids, rich in EPA (20:5 n-3), inhibit formation of COX products (e.g., TXA₂, PGE₂) derived from AA, and the newly formed TXA₃ has much less ability than TXA₂ to constrict vessels and aggregate platelets. Production of PGI₂ (prostacyclin) by endothelial cells is not reduced appreciably by increased EPA content, and the physiologic activity of newly synthesized PGI₃ is added to that of PGI₂. Administration of fish oil to humans leads to reduced production of LTB₄ by means of 5-LO in stimulated neutrophils and monocytes and induces EPA-derived LTB₅, which is far less biologically active than LTB₄. Fish oil also reduces production of IL-1β, TNF, and PAF by activated blood monocytes. Meta-analysis of randomized controlled trials of administration of fish oil to patients with RA indicate reduction in tender joint counts and duration of morning stiffness and decreased use of NSAIDs.¹¹⁹ Because NSAIDs confer an increased risk for cardiovascular disease and there is increased mortality from cardiovascular disease in patients with RA, an added benefit of fish oil for RA patients may be reduced risk of cardiovascular disease directly and by virtue of less use of NSAIDs. Fish oil supplements in the treatment of RA for 6 to 12 months result in significant reductions in number of tender joints and time of morning stiffness compared with the same measures done at baseline. Fish oil treatment allowed patients to reduce or stop NSAID treatment.¹²⁰ As noted earlier,⁶⁹ after acetylation by aspirin, COX-2 acquires the capacity to oxygenate EPA and DHA, leading to formation of novel resolvins and protectins, compounds that assist resolution of inflammation.

The other “alternative” eicosanoid precursor fatty acid, DGLA (20:3 n-6), can also be increased by administration of certain plant seed oils, notably oils extracted from the seeds of *Oenothera biennis* (evening primrose) and *Borago officinalis* (borage), which contain relatively large amounts of GLA. GLA is converted to DGLA, the immediate precursor of PGE₁, an eicosanoid with known anti-inflammatory and immunoregulating properties.¹⁰⁵ Administration of GLA to volunteers and RA patients results in increased production of PGE₁ and reduced production of the inflammatory eicosanoids PGE₂, LTB₄, and LTC₄ by stimulated peripheral blood monocytes. In addition to competing with AA for oxidative enzymes, DGLA cannot be converted to inflammatory LTs. Rather, it is converted by means of 15-LO to a 15-hydroxy-DGLA,

which has the capacity to inhibit 5-lipoxygenase and 12-LO activities. DGLA should have anti-inflammatory actions because of its capacity to reduce synthesis of oxygenation products of AA through the COX and the lipoxygenase pathways.^{117,121}

In addition to their roles as precursors of eicosanoids, essential fatty acids are important for the maintenance of cell membrane structure and function and protect the gastric mucosa from NSAID-induced injury. DGLA can also modulate immune responses in an eicosanoid-independent manner. DGLA suppresses IL-2 production by human peripheral blood monocytes in vitro, suppresses proliferation of IL-2-dependent human peripheral blood and synovial tissue T lymphocytes, and reduces expression of activation markers on T lymphocytes directly in a manner that is independent of its conversion to eicosanoids. Oral administration of oils enriched in GLA but not administration of oils enriched in linoleic acid (the parent n-6 fatty acid) or α -linolenic acid (the parent n-3 fatty acid) reduce proliferation of human lymphocytes activated through the T cell receptor complex.¹²²

Addition to peripheral blood mononuclear cells in vitro or administration of GLA in vivo reduces secretion of IL-1 β and TNF from stimulated human cells. GLA also reduces autoinduction of IL-1 β in human monocytes, preserving the protective effects of IL-1 β , while suppressing excessive production of the cytokine.^{123,124} IL-1 β and TNF are important polypeptide mediators of inflammation and joint tissue injury in patients with RA, and both cytokines are targets for biologic agents that have proven to be major advances in treatment of patients with RA. GLA suppresses acute and chronic inflammation including arthritis in several animal models, and randomized, double-blind, placebo-controlled trials of GLA in patients with RA and active synovitis indicate that GLA treatment results in statistically significant and clinically relevant reduction in signs and symptoms of disease activity compared with baseline and placebo. GLA also reduces the need for NSAID and corticosteroid therapy.¹²⁵⁻¹²⁷

EPA suppresses conversion of DGLA to AA, and a combination of EPA-enriched and GLA-enriched oils exhibits synergy in its capacity to reduce reduction of synovitis in animal models.¹²⁸ In addition, administration of black currant seed oil, which contains the n-3 fatty acid α -linolenic acid (which is converted to EPA) and the n-6 GLA, suppresses active synovitis in patients with RA.¹²⁹ These observations that particular marine and botanical oils reduce signs and symptoms of joint inflammation and have a positive impact on the profile of serum lipids suggest that both GLA- and EPA/DHA-enriched oils, or the isolated fatty acids themselves, or a combination of these might be useful treatment for diseases characterized by chronic inflammation and tissue injury. A combination of GLA and EPA may be useful therapy for RA patients. Continued study of the eicosanoids and their precursor fatty acids should delineate mechanisms by which these lipids influence the function of cells that participate in immune responses and inflammatory reactions.

Cell Recruitment and Angiogenesis

ZOLTAN SZEKANECZ • ALISA E. KOCH

KEY POINTS

Leukocyte recruitment through the vessel wall into the synovium is a crucial process in the pathogenesis of arthritis.

A number of cell adhesion molecules are involved in leukocyte extravasation.

Chemokines and their receptors are involved in the chemotaxis of neutrophils, lymphocytes, and monocytes into tissues.

Angiogenesis, the formation of new vessels, is involved in inflammation and tumor progression.

A number of soluble and cell-bound factors including chemokines and adhesion receptors may stimulate or inhibit angiogenesis.

Specific targeting of leukocyte adhesion, chemokines, and/or angiogenesis, primarily by using agents with multiple actions, may be useful for the future management of arthritis.

Inflammatory leukocytes, endothelial cells (ECs), synovial fibroblasts, and soluble mediators and cell adhesion molecules (CAMs) are involved in cell trafficking into inflammatory sites in diseases such as rheumatoid arthritis (RA)¹⁻⁵ (Figure 25-1). In arthritis, leukocyte ingress into the synovium occurs by leukocyte adhesion to ECs and then by transendothelial migration.³⁻⁵ The chemotaxis of inflammatory cells is mainly regulated by chemotactic mediators termed *chemokines*.⁶⁻¹⁰ The formation of new capillaries from preexisting vessels, termed *angiogenesis*, is a key event underlying synovial inflammation, which perpetuates the recruitment of leukocytes into the synovium.^{7,11-15} On the other hand, new vessel formation from endothelial progenitor cells (EPCs), termed *vasculogenesis*, is impaired in inflammatory arthritides.¹⁵⁻¹⁹ Several CAMs that interact with each other, as well as with soluble inflammatory mediators such as cytokines and chemokines, are involved in synovial leukocyte recruitment and angiogenesis.^{3,7,12,20}

In this chapter, we first describe the role of vascular endothelium in the pathogenesis of synovitis. The role of relevant CAMs and chemokines will then be presented followed by the description of leukocyte recruitment and angiogenesis. Finally, the clinical importance of this topic including targeting of CAMs, chemokines, and neovascularization is discussed.

ENDOTHELIAL PATHOPHYSIOLOGY IN INFLAMMATION

Endothelial cells are active players in inflammation. The vascular endothelium undergoes vasodilation and increased permeability (leakage) during synovitis.^{21,22} Increased endothelial permeability results from several mechanisms including endothelial contraction and retraction, leukocyte- or antiendothelial antibody (AECA)-mediated vascular injury and regeneration.²¹⁻²³ The endothelium secretes several inflammatory mediators resulting in vasodilatation and leakage including prostacyclin (PGI₂), nitric oxide (NO), platelet-activating factor (PAF), and others.^{21,23} In turn, endothelial cells respond to histamine, serotonin, complement factors (C3a, C5a), bradykinin, leukotrienes, PAF, and AECAs that are released in inflammatory sites.²¹⁻²³ Cytoskeletal reorganization leading to endothelial retraction may be regulated by proinflammatory cytokines such as interleukin (IL)-1, tumor necrosis factor (TNF), or interferon- γ (IFN- γ).²¹⁻²³ Among other soluble mediators, AECAs that have been detected in several inflammatory rheumatic conditions have been correlated with clinical activity and vascular damage.^{24,25}

High-endothelial venules (HEVs) are usually detected in lymphoid tissues, and they are major sites of leukocyte extravasation during the homing process.^{26,27} Such HEVs have been described at least in some synovial tissues with lymphoid neogenesis.^{28,29}

INTERCELLULAR ADHESION MOLECULES

Process of Leukocyte Extravasation in Inflammation

Adhesion of peripheral blood leukocytes to endothelium leads to the process of leukocyte transendothelial migration into inflammatory sites such as the arthritic synovium.²⁻⁴ High endothelial venules (HEVs) primarily found in lymphoid organs are also present at sites of lymphoid neogenesis in the synovium.^{3,29,30} Lymphocytes recirculate through HEVs during homing, and thus inflammatory leukocyte recruitment may be considered as “pathologic homing”^{3,4,29} (see Figure 25-1).

During leukocyte adhesion and transendothelial migration, an early, weak adhesion termed *rolling* occurs first. This step involves selectins and their ligands and leads to leukocyte activation. Activation-dependent, firm adhesion involves mostly integrin-dependent interactions, as well as the secretion of numerous chemokines. Chemokines preferentially attract endothelium-bound leukocytes^{2,20,31} (see Figure 25-1).

Figure 25-1 The process of leukocyte extravasation into the synovium.

Adhesion Receptors and Ligands

CAMs have been classified into integrin, selectin, immunoglobulin, and cadherin superfamilies^{4,32} (Table 25-1). E-, P-, and L-selectin contain a lectin-like extracellular N-terminal domain, an epidermal growth factor (EGF)-like motif, and two to nine moieties related to complement regulatory proteins.^{33,34} E- and P-selectin are expressed by ECs, whereas L-selectin is mostly expressed by leukocytes.³⁴ During leukocyte transendothelial migration, selectins mediate the initial tethering and rolling of leukocytes.^{20,34,35} E-selectin is a marker for cytokine-induced EC activation.³⁴ E-selectin ligand-1 (ESL-1) and P-selectin ligand-1 (PSGL-1) contain sialylated glycan motifs such as sialyl Lewis-X (sLe^x).³⁴ P-selectin is constitutively present on the membrane of EC Weibel-Palade bodies.³⁴ P-selectin is involved in the early phases of leukocyte-EC adhesion.³⁵ L-selectin serves as a lymphocyte homing receptor, where it mediates the physiologic recirculation of naïve lymphocytes through specialized HEV.^{32,34} However, L-selectin has also been implicated in inflammatory leukocyte recruitment.^{3,34} All three selectins are expressed in the arthritic synovium^{3,4,36} (see Table 25-1).

Integrins are $\alpha\beta$ heterodimers. Each of the common β chains is associated with one or more α subunits.^{3,32} Cell adhesion to the extracellular matrix (ECM) is mostly mediated by β_1 and β_3 , whereas intercellular adhesion is assisted through β_1 and β_2 integrins.^{2,32} β_1 and β_3 integrins are expressed on ECs, whereas β_2 integrins are leukocyte CAMs.³² Integrin-mediated adhesion and migration have been associated with arthritis.^{3,4,37} The α_1 - α_6 , α_v , α_L , α_M , α_X , and β_1 - β_7 integrin subunits have all been detected in the inflamed synovium.^{3,4,37}

The *immunoglobulin superfamily* of CAMs is a group of transmembrane glycoproteins containing one or more immunoglobulin-like motifs of 60 to 100 amino acids.³² Vascular cell adhesion molecule-1 (VCAM-1) is

Table 25-1 Relevant Members of Adhesion Molecule Superfamilies*

Adhesion Receptors	Ligands
Selectins	
L-selectin (CD62L, LAM-1)	Sialylated carbohydrates, GlyCAM-1
E-selectin (CD62E, ELAM-1)	Sialyl-Lewis-X
P-selectin (CD62P, PADGEM)	Sialyl-Lewis-X, other carbohydrates
Integrins	
$\alpha_1\beta_1$ (VLA-1)	Laminin, collagen
$\alpha_2\beta_1$ (VLA-2)	Laminin, collagen
$\alpha_3\beta_1$ (VLA-3)	Laminin, collagen, fibronectin
$\alpha_4\beta_1$ (VLA-4)	Fibronectin, VCAM-1
$\alpha_5\beta_1$ (VLA-5)	Fibronectin
$\alpha_6\beta_1$ (VLA-6)	Laminin
$\alpha_4\beta_2$ (LFA-1, CD11a/CD18)	ICAM-1, ICAM-2, ICAM-3, JAM-A
$\alpha_M\beta_2$ (Mac-1, CD11b/CD18)	ICAM-2, iC3b
$\alpha_X\beta_2$ (CD11c/CD18)	iC3b, fibrinogen
$\alpha_E\beta_7$	E-cadherin
$\alpha_4\beta_7$	Fibronectin, VCAM-1, MadCAM-1
Immunoglobulin Superfamily	
ICAM-1 (CD54)	LFA-1, Mac-1
ICAM-2	LFA-1
ICAM-3	LFA-1
VCAM-1	$\alpha_4\beta_1$, $\alpha_4\beta_7$
MadCAM-1	$\alpha_4\beta_7$, L-selectin
CD2	LFA-3
PECAM-1 (CD31)	PECAM-1, $\alpha_v\beta_3$
Cadherins	
E-cadherin (cadherin-1)	E-cadherin
N-cadherin (cadherin-2)	N-cadherin
Cadherin-11	Cadherin-11

*See text for abbreviations.

Modified from Agarwal SK, Brenner MB: Role of adhesion molecules in synovial inflammation. *Curr Opin Rheumatol* 18(3):268–276, 2006.

constitutively expressed on ECs; however, its expression is upregulated by proinflammatory cytokines.³⁸ There is abundant VCAM-1 expression in the inflamed synovium.^{3,37,39} ICAM-1, the counterreceptor for the β_2 integrins LFA-1 ($\alpha_L\beta_2$), Mac-1 ($\alpha_M\beta_2$), and $\alpha_X\beta_2$, is expressed on both ECs and leukocytes.^{3,32,40} ICAM-1 is highly expressed on ECs in inflammatory sites such as in the RA synovium.^{37,40} Among other ICAMs, ICAM-2 is constitutively expressed on ECs and may not be an activation marker.⁴⁰ ICAM-3 is a leukocyte CAM; however, it is also present on some RA synovial ECs.⁴⁰ All three ICAMs bind to β_2 integrins.^{3,40} Other members of this superfamily include CD2 and LFA-3. CD2 binds to LFA-3, and both CAMs exert abundant expression in the arthritic synovium.^{3,41} Platelet-endothelial adhesion molecule 1 (PECAM-1 or CD31) mediates homotypic adhesion by binding to another PECAM-1 molecule, as well as heterotypic adhesion by recognizing the $\alpha_V\beta_3$ integrin.^{3,32,42} PECAM-1 is a marker of endothelial activation, and it is expressed in the arthritic synovium.^{42,43}

Some other CAMs involved in leukocyte-EC adhesion underlying inflammation and associated with arthritis include CD44, vascular adhesion proteins (VAP-1 and VAP-2), endoglin, E- and N-cadherin, cadherin-11, and junctional adhesion molecules (JAMs).^{2,4,36,41,44-48} CD44 is a receptor for hyaluronate³² and is expressed on activated ECs in inflammatory sites.^{36,41,49,50} VAP-1 has originally been isolated from synovial ECs. The expression of VAP-1 is increased in RA.^{46,51} Endoglin (CD105) is a receptor for transforming growth factor (TGF)- β 1. Endoglin is involved in EC adhesion and is expressed in synovitis.^{52,53} Cadherins are primarily involved in embryogenesis; however, synovial fibroblast cadherin-11 has been implicated in arthritis as well^{4,54,55} (see Table 25-1).

CHEMOKINES AND CHEMOKINE RECEPTORS

Chemokines are small proteins that exert chemotactic activity toward leukocytes.^{9,12,56,57} There are four known chemokine supergene families based on the location of cysteine (C) residues within the chemokine structure. These families are designated as CXC, CC, CX₃C, and C chemokines; their respective chemokine receptor groups are CXCR, CCR, CX₃CR, and CR; and the current designation of chemokine members are CXCL, CCL, CX₃CR, and XCL.^{9,56} More than 50 chemokines and 19 chemokine receptors have been identified^{9,56} (Table 25-2).

Chemokine Superfamilies

Most CXC chemokines chemoattract neutrophils. Many genes coding these chemokines are clustered on chromosome 4q12-13.⁵⁷ In contrast, the genes of some CXC chemokines such as CXCL4 (platelet factor 4; PF4) and CXCL10 (IFN- γ -inducible 10-kD protein; IP-10) are located on different chromosomes, and these chemokines recruit lymphocytes and monocytes.^{56,57}

CC chemokines stimulate monocyte chemotaxis, but some members of this subclass may also recruit lymphocytes. The genes of monocyte-chemoattracting CC chemokines have been clustered to chromosome 17q11.2. In contrast,

Table 25-2 Chemokine Receptors with Their Most Relevant Ligands*

Chemokine Receptor	Chemokine Ligand
CXC Chemokine Receptors	
CXCR1	CXCL8 (IL-8)
CXCR2	CXCL8, CXCL5 (ENA-78), CXCL1 (GRO α), CXCL7 (CTAP-III)
CXCR3	CXCL10 (IP-10), CXCL4 (PF4), CXCL9 (Mig), CXCL11 (ITAC)
CXCR4	CXCL12 (SDF-1)
CXCR5	CXCL13 (BCA-1)
CXCR6	CXCL16
CXCR7	CXCL12, CXCL11
C-C Chemokine Receptors	
CCR1	CCL3 (MIP-1 α), CCL5 (RANTES), CCL7 (MCP-3), CCL23 (MPIF-1)
CCR2	CCL2 (MCP-1), CCL7
CCR3	CCL5, CCL8 (MCP-2)
CCR4	CCL17 (TARC), CCL22 (MDC)
CCR5	CCL3, CCL4 (MIP-1 β), CCL5
CCR6	CCL20 (MIP-3 α)
CCR7	CCL19 (MIP-3 β), CCL21 (SLC)
CCR8	CCL1 (I-309)
CCR9	CCL25 (TECK)
CCR10	CCL27 (CTACK), CCL28 (MEC)
C Chemokine Receptors	
XCR1	XCL1 (Lymphotactin)
C-X₃-C Chemokine Receptors	
CX ₃ CR1	CX ₃ CL1 (Fractalkine)

*See text for abbreviations.

Modified from Koch AE: Chemokines and their receptors in rheumatoid arthritis: future targets? *Arthritis Rheum* 52(3):710–721, 2005.

genes of CC chemokines recruiting lymphocytes are generally located elsewhere.^{9,56,57}

The CX₃C chemokine family has only one member, CX₃CL1 (fractalkine).^{12,56,58-60} This chemokine is chemotactic for mononuclear cells, but it also serves as an adhesion molecule.^{59,60}

The C family contains two members: XCL1 (lymphotactin) and XCL2 (single C motif 1 β ; SCM-1 β). Lymphotactin is primarily involved in the migration of T lymphocyte subsets to inflammatory sites.^{61,62}

Chemokine Receptors

The chemokines described earlier mediate their effects via 7-transmembrane domain receptors expressed on the target cells.^{56,57} Although some receptors (e.g., CXCR2, CCR1, CCR3) have multiple chemokine ligands, others (e.g., CXCR6, CCR8, CCR9) are specific receptors for one single ligand.^{9,57} Again, there may be a relationship between some chemokine receptors and the functions of their ligand(s). For example, single-ligand receptors such as CCR8 or CCR9 bind to chemokine ligands mostly exerting homeostatic functions (see later). In contrast, CXCR2, a receptor recognizing multiple CXC chemokines, plays a crucial role in inflammation and angiogenesis.^{9,63} Chemokine receptors have also been associated with various types of autoimmune inflammation. For example, RA, a mostly Th0-Th1 type disease, is associated with CXCR3 and CCR5, whereas

asthma, a known Th2 type disease, is rather associated with CCR3, CCR4, and CCR8 tissue expression.^{12,64,65}

Inflammatory and Homeostatic Chemokines: Is It a Justified Classification?

Chemokines have recently been functionally classified into these subgroups.^{10,56} As many functions of these chemokines overlap, this classification may not be really justified. Numerous CXC, CC, and CX₃C chemokines implicated in the pathogenesis of arthritis are termed *inflammatory chemokines*. These chemokines recruit mostly effector cells including monocytes, neutrophils, and T cells into tissues.^{9,10,56,66} As included in Table 25-2, there is a great body of evidence suggesting the role in RA of CXCL1 (growth-regulated oncogene α ; GRO α); CXCL4 (platelet factor 4; PF4); CXCL5 (epithelial-neutrophil activating protein 78; ENA-78); CXCL6 (granulocyte chemotactic protein 2; GCP-2); CXCL7 (connective tissue activating protein III; CTAP-III); CXCL8 (interleukin 8; IL-8); CXCL9 (monokine induced by interferon- γ ; Mig); CXCL10 (interferon- γ -inducible 10-kD protein; IP-10); CXCL12 (stromal cell-derived factor 1; SDF-1); CXCL13 (B cell-activating chemokine 1; BCA-1); and CXCL16. Among CC chemokines, CCL2 (monocyte chemoattractant protein 1; MCP-1); CCL3 (macrophage inflammatory protein 1 α ; MIP-1 α); CCL5 (Regulated upon Activation, Normal T cell Expressed and Secreted; RANTES); CCL19 (Epstein-Barr virus-induced gene 1 ligand chemokine; ELC); CCL20 (MIP-3 α); and CCL21 (secondary lymphoid tissue chemokine; SLC) have been implicated in leukocyte recruitment underlying inflammatory synovitis. Finally, CX₃CL1 (fractalkine) and XCL1 (lymphotactin) are also considered as inflammatory chemokines.^{7,9,56} Accordingly, CXCR1-CXCR6, CCR1-CCR6, and XCR1 and CX₃CR1 are involved in the pathogenesis of RA.^{7,56,67}

Homeostatic chemokines are constitutively produced in microenvironments of lymphoid or nonlymphoid tissues such as in the skin or mucosa. These chemokines promote lymphocyte homing into these tissues, a process associated with the physiologic function of the adaptive immune system. Lymphocyte recirculation is involved in antigen sampling and immune surveillance.^{10,68,69} Among CXC chemokines, CXCL12 (SDF-1), CXCL13 (BCA-1), and CXCL16, as well as their respective receptors,

CXCR4, CXCR5, and CXCR6, exert such effects.^{10,68,69} Among CC chemokines, CCL17 (TARC), CCL19 (ELC), CCL21 (SLC), CCL22 (MDC), CCL25 (TECK), CCL27 (CTACK), CCL28 (MEC), as well as their receptors, CCR4, CCR7, CCR9, and CCR10, are involved in the homeostasis of lymphoid tissues.^{56,68,69} As described earlier, among others, CXCL12, CXCL13, CXCL16, CCL19, and CCL21 have also been implicated in arthritis-associated inflammatory cell recruitment and synovial lymphoid neogenesis.^{7,10,56,67,71} The synovium is, in many ways, similar to mucosa-associated lymphoid tissues (MALT), which may explain the dual role of some chemokines in physiologic lymphocyte homing and inflammation.^{10,68,69,71}

ANGIOGENESIS AND VASCULOGENESIS IN INFLAMMATION

Angiogenesis and Vasculogenesis

Angiogenesis is the formation of new capillaries from preexisting blood vessels, whereas vasculogenesis is the outgrowth of vessels from endothelial progenitor cells (EPCs).^{7,13-15,72-77} Angiogenesis may increase the total endothelial surface and thus may enable leukocyte extravasation into inflammatory sites.^{14,15} The perpetuation of angiogenesis has been associated with inflammatory diseases such as RA or psoriasis and in malignancies.^{14,15,77,78} The outcome of such “angiogenic diseases” is dependent on the balance or imbalance between angiogenic mediators and angiostatic factors.⁷⁷ Several cytokines, growth factors, chemokines, certain CAMs, and other mediators can modulate neovascularization in inflammation^{14,15,73,77} (Table 25-3; see Figure 25-1).

Angiogenic Factors

The hypoxia-vascular endothelial growth factor (VEGF)-angiopoietin system seems to be of outstanding importance in arthritis-associated angiogenesis.^{73,79,80} VEGF is induced by hypoxia and hypoxia-inducible factors 1 and 2 (HIF-1, HIF-2) in RA.^{11,73,80-85} Significant hypoxia is characteristic of RA joints.^{73,86} Recently, the stimulatory effect of hypoxia on the angiogenic drive of RA synovial fibroblasts has been demonstrated.^{84,87} Hypoxia-inducible HIF-1 and HIF-2 are

Table 25-3 Angiogenic and Angiostatic Factors in Rheumatoid Arthritis*

	Mediators	Inhibitors
Chemokines	CXCL1, CXCL5, CXCL7, CXCL8, CXCL12, CCL2, CCL21, CCL23, CX3CL1	CXCL4, CXCL9, CXCL10, CCL21
Matrix molecules	Type I collagen, fibronectin, laminin, heparin, heparan sulfate	Thrombospondin, RGD sequence
Cell adhesion molecules	β_1 and β_3 integrins, E-selectin, P-selectin, CD34, VCAM-1, endoglin, PECAM-1, VE-cadherin, Le ^x /H, MUC18	RGD sequence (integrin ligand)
Growth factors	VEGF, bFGF, aFGF, PDGF, EGF, IGF-I, HIF-1, TGF- β †	TGF- β †
Cytokines	TNF, IL-6†, IL-15, IL-18	IL-4, IL-6†, IFN- α , IFN- γ
Proteases	MMPs, plasminogen activators	TIMPs, plasminogen activator inhibitors
Others	Angiogenin, substance P, prolactin	DMARDs, TNF blockers, angiostatin, endostatin

*See text for abbreviations. See Table 25-2 for traditional chemokine designations.

†Mediators with both proangiogenic and antiangiogenic effects.

strongly expressed in the RA synovium.^{81,84,85,87} However, hypoxia may also act via HIF-independent regulatory pathways including the peroxisome-proliferator-activated receptors (PPARs).⁸⁸ The angiopoietin-1 (Ang1)/Tie2 complex interacts with VEGF during the stabilization of newly formed blood vessels.⁸⁹ In contrast, Ang2, an antagonist of Ang1, inhibits vessel maturation.^{80,89} Ang1 and Tie2 have been detected in the RA synovium.^{90,91}

Apart from VEGF, other growth factors including fibroblast growth factors (FGF-1 and FGF-2), transforming growth factor β (TGF- β), connective tissue growth factor (CTGF), and platelet-derived growth factor (PDGF) have been implicated in synovial angiogenesis.^{1,7,14} Recently, the role of placenta growth factor (PIGF) in RA and inflammatory angiogenesis has been postulated. PIGF, like VEGF, binds to the flt-1/VEGF-R1 receptor. There is abundant expression of PIGF in the synovial tissue of arthritic mice.⁹²

Proinflammatory cytokines may exert direct angiogenic activity or may act indirectly via VEGF-dependent pathways.^{14,93} Primarily TNF, IL-1, IL-6, IL-15, IL-17, IL-18, oncostatin M, granulocyte (G-CSF), and granulocyte-macrophage colony-stimulating factors (GM-CSFs) have been implicated in synovial angiogenesis.^{14,93} Monocyte migration inhibitory factor (MIF) has been implicated in angiogenesis, as well as atherosclerosis, a major cause of death in RA patients.^{94,95}

Among numerous other angiogenic mediators not mentioned earlier, serum amyloid A (SAA), an important acute-phase reactant, has also been implicated in arthritis and angiogenesis. Interaction of SAA with formyl peptide receptor-like 1 (FPR1) induces endothelial cell proliferation, migration and angiogenesis, and synovitis.^{96,97} Further angiogenic factors include, without mentioning further details, endothelin 1 (ET-1), members of the cyclooxygenase-2 (COX-2)-prostaglandin E₂ network, angiogenin, angiotropin, pleiotrophin, platelet-activating factor (PAF), substance P, erythropoietin, adenosine, histamine, prolactin, thrombin, and sphingosine-1-phosphate (S1P).^{1,14,15,98}

The involvement of chemokines, chemokine receptors, and CAMs in angiogenesis is discussed later in context with the complex regulation of leukocyte recruitment.

Vasculogenesis in Inflammatory Conditions

EPCs are hematopoietic stem cells expressing, among other antigens, CD34, CD133, type 2 VEGF receptor (VEGFR-2 or Flk-1), and the CXCR4 chemokine receptor.^{15-17,99-101} During vasculogenesis, EPCs differentiate into mature endothelial cells.¹⁰¹ Vasculogenesis is involved in tissue development, vascular repair, atherosclerosis, and inflammation.^{15,17,99-102}

Several groups have described defective vasculogenesis related to impaired EPC numbers and functions in RA and scleroderma.^{1,16,17,102-105} Impaired vasculogenesis has been associated with increased cardiovascular morbidity and mortality in these disease states.^{1,102,106} Effective control of inflammation using corticosteroids and anti-TNF agents may stimulate EPCs and thus may restore defective vasculogenesis.^{103,107} In addition, the induction of vasculogenesis may be beneficial for patients with cardiovascular disease¹⁰⁶ and the stimulation of EPCs and vasculogenesis may also suppress premature atherosclerosis in RA.¹

INTERACTIONS AMONG ADHESION RECEPTORS, CHEMOKINES, AND ANGIOGENESIS: THE “REAL” BERMUDA TRIANGLE IN THE REGULATION OF INFLAMMATORY SYNOVITIS

Chemokines and Adhesion Receptors

The molecular mechanisms and signaling pathways of chemokine-induced CAM expression have been described. Briefly, an atypical protein kinase C, PKC- ξ , has been identified. Treatment of cells with chemokines induces PKC- ξ kinase activity through its interaction with PI3K. This leads to increased cell surface integrin expression via further signaling steps.¹

Another example for chemokine-CAM interactions is the regulation of β_3 integrin expression by CCL2 (MCP-1) through the Ets-1 transcription factor, and the ERK-1/2 cascade. This pathway is involved in both inflammation and angiogenesis.¹⁰⁸ The CCL21-CCR7 interaction results in the stimulation of LFA-1- and ICAM-1-dependent adhesion.¹⁰⁹ Stimulation of CXCR1- and CXCR2-dependent pathways in the antigen-induced arthritis (AIA) model resulted in increased neutrophil adhesion to endothelium.¹¹⁰ Thus various chemokines and chemokine receptors are involved in driving leukocyte transendothelial migration.

Chemokines and Chemokine Receptors in Angiogenesis and Vasculogenesis

Numerous CXC and CC chemokines, fractalkine, and their receptors have been implicated in angiogenesis underlying RA.^{7,12,14,111} The angiogenic nature of most CXC chemokines has been associated with the glutamyl-leucyl-arginyl (ELR) amino acid motif within their structure.⁶³ ELR-containing CXC chemokines that mediate angiogenesis include CXCL1 (GRO α), CXCL5 (ENA-78), CXCL7 (CTAP-III), and CXCL8 (IL-8).^{12,15,63,111} In contrast, the ELR-lacking CXCL4 (PF4), CXCL9 (Mig), and CXCL10 (IP-10) inhibit angiogenesis.^{8,9,39} Interestingly, some authors suggest that the effect of VEGF on endothelial cells may be, in part, mediated by CXCL10.⁴⁴ It seems that CXCL12 (SDF-1) may play a significant role in RA-associated angiogenesis despite the fact that this chemokine lacks the ELR motif.^{7,112,113} CXCL12 is also a major mediator of lymphoid neogenesis in the RA synovium.^{112,113} Hypoxia stimulates CXCL12 production by RA synovial fibroblasts.¹¹² CXCL12 has even been implicated in vasculogenesis. Virtually all EPCs express CXCR4 and migrate in response to SDF-1/CXCL12.^{42,43}

Much less evidence is available regarding the role of CC chemokines in angiogenesis. CCL2 (MCP-1) may induce endothelial cell chemotaxis in vitro and angiogenesis in vivo.^{8,47} As described earlier, CCL2-induced angiogenesis may occur via β_3 integrins.¹⁰⁸ CCL23 has been implicated in the migration of vascular endothelial cells and angiogenesis-associated matrix metalloproteinase (MMP) production.⁴⁸ In contrast, CCL21 (SLC) may exert strong angiostatic and antitumor effects.⁴⁹

CX₃CL1 (fractalkine) is involved in both angiogenesis and atherosclerosis underlying inflammatory rheumatic diseases.^{8,37,38}

Adhesion Receptors, Ligands, and Proteases in Angiogenesis and Vasculogenesis

Both CAM receptors and their extracellular matrix (ECM) macromolecule ligands mediate adhesive interactions during inflammatory neovascularization.^{4,14,114} Among ECM components, type I and other minor collagens, fibronectin, heparin, laminin, tenascin, vitronectin, and fibrinogen promote angiogenesis.^{13,114} Vasculogenesis is stimulated by the laminin matrix Matrigel.¹¹⁵ Thrombospondin-1 (TSP-1) is an angiostatic ECM component naturally produced within the RA synovium.^{14,116,117}

Among endothelial CAMs, soluble E-selectin; soluble P-selectin; the L-selectin ligand CD34; soluble VCAM-1; some endothelial β_1 , β_3 , and β_5 integrins; PECAM-1 (CD31); endoglin (CD105); and some cadherins have been implicated in angiogenesis.^{13,14,118-121} The $\alpha_v\beta_3$ integrin and the *ITGAV* gene play critical roles in inflammatory angiogenesis. The integrin has become a major target for specific therapy.^{108,120-122} Other angiogenic factors such as chemokines may act via integrin-dependent pathways.¹⁰⁸ Recently, the role of the *ITGAV* allele in angiogenesis has been further analyzed in four Caucasian sample sets. The genetic association could not be confirmed in New Zealand and Oxford (UK) sample sets, suggesting that the link between *ITGAV* gene polymorphism and RA may be limited.¹²⁰ Focal adhesion kinases (FAKs) are involved in $\alpha_v\beta_3$ integrin signaling underlying synovial inflammation and angiogenesis.¹²³ Among glycoconjugates with adhesive properties, blood group antigens Lewis-y and Lewis-H promote neovascularization.¹²⁴ JAMs (JAM-A, JAM-B, and JAM-C) have also been implicated in the adhesive processes underlying RA, as well as in synovial angiogenesis.^{45,125} Vasculogenesis also involves numerous integrins including $\alpha_v\beta_3$ and E-selectin.^{1,99,126-128}

MMPs promote angiogenesis by synovial matrix degradation.^{14,87,129,130} The role of hypoxia in MMP production is described earlier.⁸⁷ Some ADAM and ADAMTS proteases have also been implicated in inflammatory neovascularization.¹³¹⁻¹³³

Targeting Cell Adhesion, Chemokines, and Angiogenesis: Possible Therapeutic Approaches in Inflammatory Arthritides

Leukocyte recruitment inhibition may be a result of non-specific anti-inflammatory therapeutic strategies. Numerous traditional and biologic disease-modifying drugs (DMARDs) and immunosuppressive agents may, in addition to other effects, suppress leukocyte recruitment, chemokine production, and angiogenesis. Inhibition of cell adhesion and migration, angiogenesis, chemokines, and chemokine receptors using specific antibodies or purified ligands has provided an important perspective on the molecular pathogenesis of RA. In addition, some of these strategies may be included in the future therapy of arthritis.*

Inhibition of Cell Adhesion Receptors and Leukocyte-Endothelial Adhesion

Traditional DMARDs including sulfasalazine, methotrexate (MTX), and leflunomide suppressed serum and synovial fluid soluble ICAM-1, VCAM-1, and E-selectin levels in both early and established RA, as well as juvenile idiopathic arthritis (JIA).¹³⁶⁻¹³⁹ MTX and leflunomide also decrease synovial tissue CAM expression in RA.^{140,141} Statins, currently used for the treatment of dyslipidemia, may also modify endothelial function and CAM expression.¹⁴²

Infliximab therapy reduced the serum levels of soluble ICAM-1, ICAM-3, VCAM-1, and E- and P-selectin in RA and JIA.¹⁴³⁻¹⁴⁶ Adalimumab therapy resulted in the attenuation of neutrophil chemotaxis in RA.¹⁴⁷ Abatacept treatment also reduced soluble ICAM-1 and E-selectin levels in RA.¹⁴⁸ Tocilizumab also acts, in part, by inhibiting leukocyte recruitment.¹⁴⁹

Regarding specific anti-CAM targeting in humans, first an antihuman ICAM-1 antibody (enlimomab) was used to treat refractory RA. Many patients reported improvement in their status; however, repeated administration of this antibody resulted in diminished efficacy and frequent adverse events. Therefore further development of enlimomab in RA was terminated.^{150,151} Two anti-integrin strategies, the anti-LFA-1 antibody efalizumab and the LFA-3-Ig fusion protein alefacept, have been registered for the treatment of psoriasis.^{152,153} Alefacept yielded to a moderate effect in psoriatic arthritis.^{154,155} Efalizumab was withdrawn from the market in 2009 due to severe side effects. Other anti-LFA-1 antibodies have still been in preclinical arthritis studies.¹⁵⁶ Natalizumab (anti- α_4 integrin) has been tried in multiple sclerosis and Crohn's disease,^{4,69} and a monoclonal antibody to the $\alpha_4\beta_7$ integrin was administered to patients with ulcerative colitis.^{4,70} Vitaxin, a humanized antibody to the $\alpha_v\beta_3$ integrin, inhibited synovial neovascularization in animal models of arthritis, yet little efficacy was observed in a phase II human RA trial.⁷⁶ Various anti-CD44 antibodies have been tried in arthritis studies.^{157,158} These and other anti-CAM strategies may be used in other inflammatory conditions including RA.^{2,4,65}

Chemokine and Chemokine Receptor Targeting

Among traditional DMARDs, sulfasalazine and sulfapyridine inhibited chemokine production by cultured RA synovial explants.^{159,160} MTX also suppressed chemokine production in the rat adjuvant-induced arthritis (AIA) model.¹⁶¹ In MTX-treated RA patients, high levels of CCL5 correlated with sustained radiologic progression.¹⁶² MTX also decreased CCR2 expression on monocytes isolated from RA patients.¹⁶³ The combination of MTX and leflunomide inhibited the production of CCL2 (MCP-1), CCL17 (TARC), and CCL22 (MDC) in RA.¹⁶⁴ Leflunomide itself suppressed CCL2 (MCP-1) and CCL5 (RANTES) levels in RA patients.¹⁶⁵ Regarding biologics, most anti-TNF agents exert inhibitory effects on chemokine production. For example, infliximab reduced synovial expression of CXCL8 (IL-8) and CCL2 (MCP-1) in RA patients, which was associated with diminished inflammatory cell ingress into the synovium.¹⁶⁶ Treatment of RA patients with infliximab or etanercept resulted in the sustained retention of CXCR3⁺

*References 3, 4, 7, 14, 15, 72, 76, 134, 135.

T cells in the circulation indicating a clearance of these cells from the synovium.¹⁶⁷ In recent studies, infliximab or etanercept also suppressed the release of CXCL1 (GRO α), CXCL8 (IL-8), CXCL10 (IP-10), CXCL16, CCL2 (MCP-1), CCL5 (RANTES), CCL20 (MIP-3 α), and CX₃CL1 (fractalkine).^{166,168-175} Infliximab also reduced chemokine production in response to *Mycobacteria* in RA patients, which may have relevance for increased incidence of tuberculosis during anti-TNF therapy.¹⁷⁶ Among newer biologics, tocilizumab also acts by suppressing CAM and chemokine production.¹⁴⁹ Depletion of B cells by rituximab also interferes with the CXCL8 (IL-8) network.¹⁷⁷ Interestingly, antioxidants such as *N*-acetyl-L cysteine and 2-oxothiazolidine-4-carboxylate inhibited mRNA expression of CXCL8 (IL-8) and CCL2 (MCP-1) by cytokine-pretreated human synovial fibroblasts.¹⁷⁸

Regarding direct chemokine receptor inhibition, most human trials using small molecule inhibitors of chemokine receptors failed.¹⁷⁹⁻¹⁸¹ For example, MLN3897, an oral CCR1 antagonist, in combination with MTX had no significant clinical efficacy in RA.¹⁷⁹ Similarly, SCH351125¹⁸⁰ and AZD5672,¹⁸¹ oral CCR5 inhibitors, did not give any clinical benefit in RA. Yet numerous CCR1, CCR2, and CCR5 antagonists are in clinical development in arthritis, as well as other inflammatory diseases.¹⁸²⁻¹⁸⁴

A limited number of human antichemokine studies have been done. There has been one trial using an anti-CXCL8 (IL-8) antibody in RA, but results of this trial were not published and the further development of this compound was terminated.⁹

Antibodies or peptide inhibitors against CXCL4 (PF4), CXCL5 (ENA-78), CXCL8 (IL-8), CXCL10 (IP-10), CXCL16, CCL2 (MCP-1), and CX₃CL1 (fractalkine) have been tried successfully in animal models of arthritis,^{56,67,134,185-187} but none of these agents has yet reached human development. Our group assessed a neutralizing

polyclonal anti-CXCL5 antibody administered intravenously to rats using the AIA model. The antibody injected before the onset of arthritis attenuated the severity of the disease. This antibody also prevented the ingress of IL-1-expressing leukocytes into the synovium.¹⁸⁶ Regarding chemokine receptor targeting in rodents, CXCR2, CXCR4, CCR1, and CCR5 antagonists have been tried in these animal models.^{9,134,188,189} Bicyclam, also known as AMD3100, a highly selective antagonist of CXCL12 (SDF-1)/CXCR4, inhibited inflammation and angiogenesis.¹⁸⁹ The failure of numerous oral CCR1 and CCR5 antagonists in human trials is discussed earlier.

Some studies have addressed the use of combined chemokine blockade. For example, a combination of CCL2 (MCP-1) and CXCL1 (GRO α) inhibition resulted in more pronounced arthritis suppression than CCL2 blockade alone in a murine AIA model.¹⁹⁰ Certainly, there may be increased toxicity using combined strategies.⁹ Hence chemokine or chemokine receptor blockade using antibodies or other inhibitors may be promising for future therapies.

Angiogenesis Targeting: Use of Angiostatic Compounds

Angiogenesis can be inhibited by either blocking the action of angiogenic mediators or by using angiostatic compounds (Table 25-3, Figure 25-2). Focusing on leukocyte recruitment, anti-CAM antichemokine strategies are discussed earlier.

A number of currently used antirheumatic agents such as dexamethasone, chloroquine, sulfasalazine, MTX, azathioprine, cyclophosphamide, leflunomide, thalidomide, minocycline, anti-TNF agents, and possibly cyclosporine A nonspecifically suppress angiogenesis.^{13,14,191}

VEGF inhibitors have been tried in arthritis and cancer studies.^{72,76,80,135} One can inhibit VEGF-mediated

Figure 25-2 Steps of angiogenesis: its mediators and possible angiostatic targeting strategies.

neovascularization by using monoclonal antibodies to VEGF or VEGF receptors (VEGFR), soluble VEGFR constructs, small molecule VEGF and VEGFR inhibitors, or inhibitors of VEGF and VEGFR signaling.^{72,76,192} VEGF or VEGFR inhibition has been included in arthritis trials.^{192,193} The VEGF tyrosine kinase inhibitor vatalanib (PTK787) and an anti-VEGFR1 antibody exerted significant angiostatic and antiarthritic effects in animal models of arthritis.^{194,195} A soluble VEGFR1 chimeric protein dose-dependently inhibited synovial endothelial proliferation.¹⁹³ Soluble Fas ligand (sFasL, CD178) is a functional inhibitor of the 165 amino acid form of VEGF (VEGF165). sFasL inhibits angiogenesis in arthritis.¹⁹⁶

The involvement of PPARs in hypoxia-induced VEGF production is discussed earlier. PPAR γ ligands rosiglitazone and pioglitazone inhibited VEGF-induced angiogenesis.¹⁹⁷ Moreover, pioglitazone also improved joint and skin symptoms in psoriatic arthritis.¹⁹⁸ Hypoxia-induced and VEGF-mediated neovascularization may also be targeted by the inhibition of HIFs.^{85,87} For example, YC-1, a superoxide-sensitive stimulator of soluble guanylyl cyclase that also inhibits HIF-1, has been developed for the treatment of hypertension but may potentially be used to suppress inflammatory angiogenesis.¹⁹⁹ The synthetic benzophenone analogue, BP-1, a HIF-1 α inhibitor, ameliorated AIA in rats.²⁰⁰ In a recent trial, HIF-1 signaling was targeted in inflammatory bowel disease.²⁰¹ RA synovial fibroblasts enhanced myeloid cell recruitment and angiogenesis in synovial tissues engrafted into immunodeficient mice. In this model, targeting HIF-1 α expression by either siRNA or by the small molecule inhibitor chetomin significantly reduced these processes.²⁰²

The role of the Ang1/Tie2 system in arthritis is described earlier.^{90,91} A soluble Tie2 receptor transcript delivered via an adenoviral vector to mice attenuated the incidence and severity of collagen-induced arthritis (CIA).²⁰³

Regarding the targeting of other angiogenic growth factors, imatinib mesylate is a specific inhibitor of PDGF receptor activation. This compound inhibited pannus formation and the development of arthritis in the murine CIA model.^{204,205} The PPAR γ agonists rosiglitazone and pioglitazone suppressed not only VEGF- but also bFGF-mediated neovascularization.¹⁹⁷ An anti-flt-1 hexapeptide, GNQWFI abrogated PlGF-induced angiogenesis, cytokine production, and the development of CIA in mice.⁹²

Matrix metalloproteinases (MMPs) and plasminogen activators are involved in matrix degradation underlying leukocyte recruitment and angiogenesis. Numerous protease inhibitors including tissue inhibitors of metalloproteinases (TIMPs) and plasminogen activator inhibitors (PAIs) that antagonize the effects of proteases have been tried in angiogenesis models.^{206,207}

Anticytokine therapy currently used to treat arthritides may influence angiogenesis, as well as cell adhesion and chemokines. For example, TNF blockade by infliximab reduced VEGF expression and vascularity within the RA synovium.²⁰⁸ Infliximab also reduced synovial Ang1 and Tie2 expression.²⁰⁹ The anti-IL-6 receptor antibody tocilizumab also decreased serum levels of VEGF in RA.²¹⁰

IL-4 and IL-13 are anti-inflammatory and angiostatic cytokines in RA.²¹¹⁻²¹³ IL-4 suppresses VEGF release by RA synovial fibroblasts.²¹¹ IL-4 and IL-13 gene transfer

inhibited synovial inflammation and angiogenesis in rats.^{212,213}

Antibiotic derivatives including minocycline, fumagillin analogues, deoxyspergualin, roxithromycin, and clarithromycin also inhibit the release of VEGF and other angiogenic mediators and thus neovascularization.²¹⁴⁻²¹⁶ Synthetic fumagillin derivatives TNP-470 and PPI-2458 inhibit VEGF, as well as methionine aminopeptidase-2, an enzyme involved in angiogenesis.²¹⁵ In human RA trials minocycline, roxithromycin, and clarithromycin exerted moderate but significant clinical effects.²¹⁶⁻²¹⁸

Among other angiogenic mediators, endothelin-1 antagonists currently used in the treatment of primary and scleroderma-associated pulmonary hypertension may also exert antiangiogenic effects.⁷⁵ Angiostatin, a fragment of plasminogen; endostatin, a fragment of type XIII collagen; and their derivatives block $\alpha_v\beta_3$ integrin-dependent angiogenesis.²¹⁹⁻²²² Angiostatin, endostatin, and kallistatin gave promising results in cancer therapy trials and preclinical arthritis studies.^{76,219,222-225} Type IV collagen derivatives including arresten, canstatin, and tumstatin also inhibit neovascularization.²²⁶ 2-Methoxyestradiol (2-ME) is a natural metabolite of estrogen with low affinity for estrogen receptors. 2-ME inhibits angiogenesis by disrupting microtubules and by suppressing HIF-1 α activity.²²⁷ In recent preclinical studies, 2-ME suppressed arthritis in animal models.^{228,229} The microtubule destabilizer paclitaxel (Taxol), used in cancer therapy, inhibits HIF-1 α expression and activity and thus indirectly blocks angiogenesis. Taxol has been found effective and safe in a phase I RA clinical trial.⁷⁶ Thrombospondin-1 (TSP-1) is a proinflammatory but angiostatic ECM component that binds integrins.^{230,231} In one study, a TSP-1-derived peptide suppressed synovial inflammation and angiogenesis in a rat arthritis model.¹¹⁶ The role of sphingosine-1-phosphate (S1P) in angiogenesis is discussed earlier.²³² Chemical lead 2 (CL2, Edg-1) is a non-S1P analogue. CL2 inhibited tube formation in endothelial cultures, suppressed VEGF-induced angiogenesis, and attenuated arthritis in the CIA model.²³²

Recently, an emerging number of compounds in traditional Chinese and Korean medicine have been implicated in angiogenesis research. These compounds may also have angiostatic effects in arthritis. For example, scopolin, a coumarin derivative found in the stems of *Erycibe obtusifolia Benth* was injected intraperitoneally in the rat AIA model. Scopolin reduced paw swelling and arthritis scores and reversed body weight loss in the rats. This antiarthritic effect was accompanied by the suppression of synovial tissue VEGF, bFGF expression, and reduced angiogenesis.²³³ Celastrol, an active ingredient of *Tripterygium wilfordii*, also known as "Thunder God Vine," has been widely used to treat RA in China. In a recent study, celastrol exerted anti-angiogenic effects in various angiogenesis assays. Celastrol also inhibited endothelial cell migration and VEGFR1 and VEGFR2 expression.²³⁴ The flavonol-rich fraction of *Rhus verniciflua Stokes* (RVHxR) and its active ingredient, fisetin, inhibited the proliferation and cytokine production of RA synovial fibroblasts, as well as VEGF release. RVHxR and fisetin acted via the inhibition of ERK and JNK phosphorylation.²³⁵

The restoration of impaired vasculogenesis is also crucial in arthritis and scleroderma patients.^{15,16,18,105} As discussed

earlier, corticosteroids and anti-TNF agents may stimulate EPCs and thus normalize vasculogenesis in RA.^{103,107} The CXCL12 (SDF-1) inhibitor bicyclam (AMD3100) mobilized EPCs in mice.¹⁸⁹ As the number of EPCs correlate with the improvement of DAS28 in RA,¹⁰⁷ the suppression of systemic inflammation and disease activity by any means would improve vasculogenesis.

SUMMARY

In this chapter we have discussed the putative role of leukocyte-endothelial adhesion, CAMs, chemokines, chemokine receptors, angiogenesis, and vasculogenesis in leukocyte recruitment underlying inflammation. The presence of various CAM pairs and interacting chemokines may account for the diversity and specificity of leukocyte recruitment. A number of soluble and cell-bound factors may stimulate or inhibit angiogenesis. The outcome of inflammatory and other “angiogenic diseases” such as various forms of arthritis depends on the imbalance between angiogenic and angiostatic mediators. Some CAMs and chemokines, as well as growth factors, proteases, antibiotics, and other agents are also involved in neovascularization. Impaired EPC function and vasculogenesis have been associated with active arthritis. There have been several attempts to therapeutically interfere with the cellular and molecular mechanisms described earlier. Specific targeting of leukocyte adhesion, CAMs, chemokines, chemokine receptors, and/or angiogenesis, as well as the restoration of defective vasculogenesis, may be useful for the future management of arthritis and other inflammatory diseases.

KEY POINTS

Cytokines are peptides that have a fundamental role in communication within the immune system and in allowing the immune system and host tissue cells to exchange information.

Cytokines act via binding to a receptor that in turn sends a signal to the recipient cell that leads to a change in function or phenotype. Such signal cascades are complex and integrate a variety of environmental factors.

Cytokines exist in broad families that are structurally related but exhibit diverse function (e.g., tumor necrosis factor [TNF]/TNF receptor superfamily, IL-1 superfamily, IL-6 superfamily).

Cytokine targeting has proven effective in many rheumatic diseases, particularly therapeutics that inhibit TNF and IL-6—many more cytokines are currently under investigation as therapeutic targets or as therapeutic agents.

Immune function depends on the biologic activities of numerous small glycoprotein messengers termed *cytokines*. Originally discovered and defined on the basis of their functional activities, cytokines are now designated primarily by structure. Typically, cytokines exhibit broad functional activities that mediate not only effector and regulatory immune function but also in wider effects across a range of tissues and biologic systems. As such, cytokines play a role in not only host defense but also a variety of normal physiologic and metabolic processes. By this means they integrate de facto host defense and host metabolic function. The Human Genome Project has assisted the discovery of numerous cytokines, posing considerable challenges resolving their respective and synergistic functions in complex tissues in health and disease. Such understanding is, however, essential with the increasing application of cytokine-targeted therapies in the clinic. This chapter reviews general features of cytokine biology and the cellular and molecular networks within which cytokines operate; the focus is on the effector functions of cytokines that are important in chronic inflammation and in rheumatic diseases.

CLASSIFICATION OF CYTOKINES

In the absence of a unified classification system, cytokines are variously identified by numeric order of discovery (currently interleukin [IL]-1 through IL-37); by a given functional activity (e.g., tumor necrosis factor [TNF], granulocyte colony-stimulating factor); by kinetic or functional role in inflammatory responses (early or late, innate or adaptive,

proinflammatory or anti-inflammatory) by primary cell of origin (monokine = monocyte derivation; lymphokine = lymphocyte derivation); and, more recently, by structural homologies shared with related molecules. Superfamilies of cytokines share sequence similarity and exhibit homology and some promiscuity in their reciprocal receptor systems (Figure 26-1). They do not exhibit functional similarity. Cytokine superfamilies also contain important regulatory cell membrane receptor-ligand pairs, reflecting evolutionary pressures that use common structural motifs in diverse immune functions in higher mammals. The TNF/TNF receptor superfamily¹ contains immunoregulatory cytokines including TNF, lymphotoxins, and cellular ligands such as CD40L, which mediates B cell and T cell activation, and FasL (CD95), which promotes apoptosis. Similarly, the IL-1/IL-1 receptor superfamily² contains cytokines including IL-1 β , IL-1 α , IL-receptor antagonist, IL-18, IL-33, IL-36 (α, β, γ), IL-36 receptor antagonist, and IL-37 (α, β), which mediate physiologic and host-defense function, but this family also includes the Toll-like receptors, a series of mammalian pattern-recognition molecules with a crucial role in recognition of microbial species early in innate responses.

ASSESSING CYTOKINE FUNCTION IN VITRO AND IN VIVO

Although originally identified by bioactivity and quantified by bioassay, most cytokines are now identified via homologous receptor binding or sequence homology in gene databases. They are quantified in biologic solutions by enzyme-linked immunosorbent assay, multiplex technology, or meso platform techniques, the latter allowing many (25 to 360) cytokines to be measured in single, small sample volumes ($\approx 20 \mu\text{L}$). Function is thereafter assessed by identification of the cellular source of cytokine, determination of native stimuli, characterization of receptor distribution, and determination of function in target cells. Experimental in vivo models use the addition of neutralizing cytokine-specific antibodies or soluble receptors (often as fragment crystallizable fusion or pegylated proteins to enhance half-life and modulate functional interaction with leukocytes) to modulate cytokine function. Genetically modified knock-out and knock-in mice (cytokine or receptor modified by embryonic stem cell technology) or transgenic mice (tissue/cell lineage-specific overexpression) have proven particularly useful. Conditional gene-targeting approaches (e.g., using the Cre system) facilitate circumvention of embryonic lethal deficiencies or allow kinetic evaluation of the relative contribution of a cytokine throughout a response. Moreover, recent multiphoton microscopic techniques have

Figure 26-1 Cytokine receptors. Cytokines, chemokines, and growth factors bind to many different types of surface receptors in the cell membrane. The figure shows several distinct families and representative ligands that are critical. Each receptor type is associated with distinct signaling mechanisms that orchestrate and integrate the cellular response after ligand binding. IL-1, interleukin-1; TGF- β , transforming growth factor-beta; TNF, tumor necrosis factor.

allowed the additional evaluation of cytokine contributions in three-dimensional tissue orientation and in real time *in vivo*. Cytokine function is normally assessed *in vitro* in primary or transformed cell lines stimulated in the presence or absence of recombinant cytokine or specific anticytokine antibody or soluble receptor. Gene knock-down approaches using siRNA or antisense oligonucleotides are also increasingly employed.

This general approach has been crucial in rheumatic disease research. Studies in which cytokine addition and neutralization occur in synovial tissue explants or disaggregated cell populations, chondrocyte explants, bone culture models, skin, and renal tissue explants and cell lines have been informative. *Ex vivo* methodologies now include intracellular fluorescence activated cell sorter methods, confocal and laser scanning microscopy, and quantitative histologic evaluation using automated image analysis. Such modalities, particularly when employed in human therapeutic cytokine neutralization studies in which inflammatory tissues are obtained throughout therapeutic interventions, advance the understanding of basic and pathogenetic cytokine function. Analysis of synovial biopsy specimens obtained before and after infliximab, adalimumab, abatacept, rituximab, IL-1Ra, IL-10, and interferon (IFN)- β administration in rheumatoid arthritis provides the strongest evidence for the success of this approach.^{3,4}

CYTOKINE RECEPTORS

Cytokine receptors exist in structurally related superfamilies and comprise high-affinity molecular signaling complexes that assist cytokine-mediated communication (see Figure 26-1). Such complexes often include heterodimeric or heterotrimeric structures that use unique, cytokine-specific recognition receptors together with common receptor chains shared across a cytokine superfamily. Examples

include the use of the common γ chain receptor by IL-2, IL-4, IL-7, IL-9, IL-15, IL-21, and glycoprotein 130 (gp130) by members of the IL-6 family.^{5,6} Alternatively, distinct receptors may use shared signaling domains. Homologous death domains are found in many TNF-receptor family members. Similarly, the IL-1 signaling domain is common to not only IL-1R but also other IL-1R superfamily members including IL-18R, IL-33R, and the Toll-like receptors.² Signaling pathways dependent on these are discussed in detail elsewhere. It has been recognized more recently that unrelated cytokine receptor systems exhibit close cross-communication on the cell membrane, allowing a cell to integrate a variety of external stimuli to optimize signaling pathways and the cellular response in real time in a changing environment. Although best elucidated in the epidermal growth factor receptor system, this also has been identified for members of the common γ chain signaling family.

Cytokine receptors can operate via several mechanisms. Membrane receptors, with intracellular signaling domains intact, can transmit signals to the target cell nucleus after soluble cytokine binding and promote effector function (Figure 26-2). Membrane receptors may bind cell membrane cytokines assisting cross-talk between adjacent cells. Membrane-bound and soluble cytokines may promote distinct receptor function. Useful exemplars exist relevant to the rheumatic diseases. Thus TNF binds TNF-RI and TNF-RII with similar affinity, but it has a slower rate of dissociation from TNF-RI. Soluble TNF may dissociate rapidly from TNF-RII to bind TNF-RI, promoting preferential signaling by the latter (ligand passing).¹ In contrast, during cell-cell contact, stable TNF/TNF-RI and TNF/TNF-RII complexes form, allowing for differential signaling contribution by TNF-RI and TNF-RII.

Cytokine receptor/cytokine complexes also may operate *in trans*, whereby component parts of the ligand-receptor

Figure 26-2 Cytokine signaling and regulation. After ligand binding, cytokine receptors activate a series of signaling molecules that are associated with the cytoplasmic portion of the receptor or the plasma membrane. In this figure Janus kinases (JAK) or spleen tyrosine kinase (SYK) are activated, which in turn phosphorylate additional cytoplasmic molecules (signal transducer and activator of transcription [STAT]; mitogen-activated protein kinase [MAPK]) then can migrate to the nucleus and either directly or through additional intermediaries activate gene transcription. mRNA levels can also be regulated after transcription by microRNAs. Ultimately, the translated proteins can be processed and released by the cell into the microenvironment or presented on the plasma membrane to other cells.

complex are derived from adjacent cells. IL-15/IL-15R α complexed on one cell may bind IL-15R β/γ on another.⁷ Receptors also exist in soluble form, derived either from alternative mRNA processing to generate receptor-lacking transmembrane or intracellular domains or from enzymatic cleavage of receptor from the cell surface (e.g., sTNF-R, sIL-1R1). Soluble receptors may act to antagonize cytokine function, regulating responses. Soluble receptors also may preform complexes with cytokine to promote subsequent ligand-receptor assembly on the target cell membrane and enhance function. Soluble receptors can deliver cytokine to the cell membrane via ligand passing. IL-6 provides a particularly important example given its core role in a range of rheumatic disorders. IL-6 binds to a heterodimeric receptor (IL-6R and gp130) and provokes cell activation thereby via conventional signal pathways that involve STAT3. Thus IL-6 may activate a cell expressing the combination of IL-6R and gp130 by conventional (cis) signaling. In addition, however, circulating soluble IL-6R may form functional gp130/IL-6R effector complexes on any cell expressing membrane gp130 and by this means confer on circulating IL-6 the ability to exert broad functional effects (trans signaling). Finally, it is now recognized that some cytokines with the capacity to be retained in the membrane may themselves function as signaling molecules (reverse signaling).

The precise intracellular signal pathways whereby cytokines mediate their effects have now been elucidated and reveal a multiplicity of potential therapeutic targets (Figure

26-3). This is exemplified in the role of the Janus kinases (JAK) and their downstream transcriptional factors (e.g., STATs) in mediating signals serving those cytokines that bind to common gamma chain, or to gp130 receptor. Similarly the mitogen-activated protein (MAP) kinases mediate signals that integrate cell responses to stress, cytokines, and proliferation factors. Spleen tyrosine kinase (Syk) is an additional kinase that mediates the effector function of immunoglobulin Fc receptor and the B cell receptor and interacts with many downstream cytokine-mediated signal pathways. Finally, the NF κ B pathway is central to the function of the TNF receptor and to those pathways that mediate signals of Toll-like receptors and IL-1 superfamily members. There is considerable interest in targeting upstream members of the MAP kinase family, JAKs, and Syk, with the latter two demonstrating efficacy in clinical trials focused on rheumatoid arthritis. One key question will be whether the broader cytokine-regulating effects of signal transduction inhibitors will have an acceptable safety profile compared with biologics that target individual cytokines or receptors.

REGULATION OF CYTOKINE EXPRESSION

Cytokines are synthesized in the Golgi apparatus and may traffic through the endoplasmic reticulum to be released as soluble mediators, or they may remain membrane bound, or

Figure 26-3 Cytokine signaling pathways. Numerous signaling mechanisms participate in transmitting information from the cell surface to the cytoplasm or the nucleus. Several representative examples are shown. In each case, a cytoplasmic amplification system permits modulating and integrating environmental stresses to orchestrate the appropriate cellular response. ERK, extracellular receptor kinase; IKK, inhibitor of κ B kinase; JAK, Janus kinase; JNK, Jun N-terminal kinase; MAPK, mitogen-activated protein kinase; NF κ B, nuclear factor κ B; STAT, signal transducer and activator of transcription; SYK, spleen tyrosine kinase.

they may be processed into cytosolic forms that can traffic intracellularly, even returning to the nucleus, where they can act as transcriptional regulators. Cytokines mediate autocrine function either through release or membrane expression and immediate receptor ligation on the source cell or intracellularly within the source cell. Alternatively, cytokines operate in a paracrine manner, allowing cellular communication beyond that assisted by local cell-cell contact. The distance and kinetics for effective function may be limited⁸; however, by numerous factors including physicochemical considerations of the peptide structure itself, extracellular matrix binding (e.g., to heparan sulfate), enzymatic degradation (e.g., serine protease degradation of IL-18), or the presence of soluble receptors (e.g., TNF/soluble TNF-RI and TNF-RII, IL-2/soluble IL-2R α) or novel cytokine-binding proteins (e.g., IL-18/IL-18 binding protein) in the inflammatory milieu.

Numerous factors promote cytokine expression *in vivo* (Figure 26-4) including cell-cell contact, immune complexes/autoantibodies, local complement activation, microbial species and their soluble products (particularly via TLR and nucleotide oligomerization domain [NOD]-like receptors [NLRs]), reactive oxygen and nitrogen intermediates, trauma, shear stress, ischemia, radiation, ultraviolet light, extracellular matrix components, DNA (mammalian or microbial), heat shock proteins, electrolytes (e.g., K⁺ via P₂X₇ receptors), and cytokines themselves operating in autocrine loops. Commonly used *in vitro* stimuli include many of these and chemical entities including phorbol esters, calcium ionophores, lectins (e.g., phytohemagglutinin), and receptor-specific antibodies such as anti-CD3 and

anti-CD28 for T cell activation or anti-immunoglobulin and anti-CD40 for B cells.

Cytokine regulation within the cell can be usefully considered at several levels (see Figure 26-2). Transcriptional regulation depends on the recruitment of discrete transcription factors to the cytokine promoter region. Transcription factor binding allows for numerous signal pathways to regulate cytokine expression across a range of stimuli. Several transcription factors (e.g., nuclear factor κ B [NF κ B], activator protein-1 [AP-1], nuclear factor of activated T cell) are

Figure 26-4 Overview of cytokine regulatory function. Numerous and diverse stimuli (1) promote cytokine expression arising either from novel gene expression (2) or from activation of preformed cytokine (3). Cytokine proteins are thereafter expressed in the cytosol, on the cell membrane, or in soluble form in the extracellular environment (4). Cytokines bind to reciprocal receptors that reside either on the membrane of a target cell or in the soluble phase (5). Membrane receptors, on cytokine ligation, signal to the recipient cell nucleus (6) and drive novel gene expression to promote effector function. Each phase of cytokine function offers rich therapeutic potential. IC, immune complexes.

crucial in cytokine production. Inhibition of NF κ B activity using either chemical inhibitors or adenoviral delivery of regulatory peptides leads to amelioration of inflammatory synovitis in vivo and in vitro.⁹ Sequence polymorphism within cytokine promoters offers potential for differential cytokine expression between individuals that could confer selective advantage against infection but could also increase susceptibility to, or progression of, autoimmunity. This is best exemplified in the TNF and IL-1 promoters.^{10,11} Single nucleotide polymorphisms in the TNF promoter region (e.g., -308) are associated with altered TNF release on leukocyte stimulation in vitro. Similarly, homozygotes for the A2 allele at +3954 in the IL-1 β gene produce more IL-1 β with lipopolysaccharide stimulation. Polymorphisms also exist in the IL-1Ra gene, rendering the functional significance of individual single nucleotide polymorphisms on IL-1 protein release difficult to interpret. In general, the net effect of haplotypes may be more important at the functional level or only play a role in the context of networks where multiple minor polymorphisms can synergize, particularly when their relevance to disease entities is considered.

Posttranscriptional regulation is important in determining longevity of cytokine expression. This regulation may operate by promoting translational initiation, mRNA stability, and polyadenylation. AU-rich elements (AREs) within the 5' or 3' untranslated regions (UTRs) of cytokine mRNA are crucial for stability; 3' UTR AREs down-regulate TNF expression such that transgenic knockin mice that lack TNF AREs develop spontaneous inflammatory arthritis and bowel disease.¹² Regulatory proteins bind AREs to mediate such effects. HuR and AUF1 exert opposing effects, stabilizing and destabilizing ARE-containing transcripts.¹³ TIA-1 and TIAR have been identified as RNA recognition motif family members¹⁴ that function as translational silencers. Macrophages from TIA-1-deficient macrophages produce excess TNF, whereas TIA-1-deficient lymphocytes exhibit normal TNF release, suggesting distinctions in mRNA regulation in discrete cell types.¹⁵ Alternatively, cytokines may generate stable mRNA a priori to assist subsequent rapid response in tissues. IL-15 mRNA 5' UTR contains 12 AUG triplets that significantly reduce the efficiency of IL-15 translation. Deletion of this sequence permits IL-15 secretion. IL-15 mRNA can produce a 48 amino acid signal peptide that allows IL-15 release and a shorter 21 amino acid signal peptide that targets intracellular distribution. IL-15 forms thus generated exhibit discrete functions.¹⁶

Posttranslational regulation also modulates cytokine expression via several mechanisms. Patterns of glycosylation are important for cytokine function and may regulate intracellular trafficking.¹⁶ Modified leader sequences can alter intracellular trafficking of cytokines. Some cytokines are translated without functional leader sequences. Their secretion depends on nonconventional secretory pathways that are poorly understood. IL-1 β employs, among other pathways, a purine receptor-dependent pathway (P₂X₇) for cellular release.¹⁷ Enzymatic activation of cytokines is common, whereby nonfunctional promolecules are cleaved to generate functional subunits. Examples include the cleavage by caspase 1 of pro-IL-1 β to generate active IL-1 β and, similarly, of pro-IL-18 to generate an active 18-kD species.¹⁸

This is an organized process both sequentially (in time) and by orientation within the cell (in space). IL-1 processing occurs in a protein complex within the cytosol termed the *inflammasome*. The latter has recently attracted considerable interest as a therapeutic target in conditions such as crystal-induced arthritis and in diseases that arise from mutations in certain inflammasome genes (e.g., cryopyrin) (see Chapters 18, 94, and 97).

Alternative processing pathways for cytokines include the serine proteases, proteinase 3 and elastase, and adamalysin family members. Enzyme cleavage pathways operate within and outside cells, providing for extracellular cytokine activation. Similarly, cell membrane enzymes serve to cleave membrane-expressed cytokine. Members of the adamalysin family regulate TNF release; TNF-converting enzyme cleaves and mediates the release of TNF and its receptors.¹⁹ Extensive molecular machinery exists to regulate tightly not only the production and stability of cytokine mRNA but also its translation and cellular expression and distribution. At each level, opportunities exist for intervention and therapeutic cytokine modulation.

EFFECTOR FUNCTION OF CYTOKINES

Cytokines possess pleiotropic and potent effector function in acute and chronic inflammatory responses. The identity, receptor specificity, and key effects of cytokines understood to have particular importance in pathogenesis of human autoimmunity and chronic inflammation are summarized in Tables 26-1 through 26-8.

Cytokines in Acute Inflammation

Cytokines operate at every stage in the crucial early events that promote acute inflammation. Cells that make up the innate immune response including neutrophils, natural killer cells, macrophages, mast cells, and eosinophils all produce and respond to cytokines generated within seconds of tissue insult. Cytokines prime leukocytes for response to microbial and chemical stimuli, upregulate adhesion molecule expression on migrating leukocytes and endothelial cells, and amplify the release of reactive oxygen intermediates, nitric oxide, vasoactive amines, and neuropeptides, as well as the activation of kinins and arachidonic acid derivatives, prostaglandins, and leukotrienes, which regulate cytokine release. Similarly, cytokines regulate the expression of complement processing and membrane defense molecules, scavenger receptors, NLR, and TLRs. Cytokines, particularly IL-1, TNF, and IL-6, are crucial in driving the acute-phase response. Tables 26-1 through 26-8 provide descriptions of the function of cytokines expressed within the acute inflammatory response.

Cytokines in Chronic Inflammation

Cytokines critically modulate the cellular interactions that characterize chronic inflammation. Studies using real-time image analytic techniques such as two-photon microscopy and confocal scanning suggest continuous cellular motility during inflammation. Inflammatory lesions might properly be considered fluid states in which individual cells under

Table 26-1 Interleukin-1 Superfamily Cytokines with Roles in Rheumatic Disease

Cytokine	Size (kD)*	Receptors	Major Cell Sources	Key Functions
IL-1 β	35 (pro)	IL-1RI	Monocytes; B cells; fibroblasts; chondrocytes; keratinocytes	Fibroblast cytokine, chemokine, MMP, iNOS, PG release \uparrow
	17 (active)	IL-1RAcP IL-1RII (decoy)		Monocyte cytokine, ROI, PG \uparrow Osteoclast activation Chondrocyte GAG synthesis \downarrow ; iNOS, MMP, and aggrecanase \uparrow Endothelial adhesion-molecule expression Similar to IL-1 β
IL-1 α	35 (pro) \dagger	IL-1RI	Monocytes; B cells; PMNs; epithelial cells; keratinocytes	
	17 (active)	IL-1RAcP IL-1RII (decoy)		Autocrine growth factor (e.g., keratinocytes)
IL-1Ra	22	IL-1RI IL-1RAcP IL-1RII	Monocytes	Antagonize effects of IL-1 β and IL-1 α
IL-18	23 (pro)	IL-18R	Monocytes; PMNs; dendritic cells; platelets; endothelial cells	T cell effector polarization (Th1 with IL-12/Th2 with IL-4)
	18 (active)	IL-18R $\beta\alpha$		Chondrocyte GAG synthesis \downarrow ; iNOS expression NK activation; cytokine release; cytotoxicity Monocyte cytokine release; adhesion molecule expression PMN activation; cytokine release; migration Endothelial cells—proangiogenic Promote Th2 cell activation, mast cell activation, and cytokine production
IL-33	30 (pro)	ST2L	Epithelial cells; monocytes; smooth muscle cells; keratinocytes	
	18 (active)	IL-1RAcP		

*Pro forms cleaved to active moieties by proteases including caspase-1, calpain, elastase, and cathepsin G.

\dagger Pro-IL-1 α retains bioactivity before cleavage.

GAG, glycosaminoglycan; iNOS, inducible nitric oxide synthase; MMP, matrix metalloproteinase; NK, natural killer; PG, peptidoglycan; PMN, polymorphonuclear neutrophil; ROI, reactive oxygen intermediates.

Table 26-2 Tumor Necrosis Factor Superfamily Cytokines* with Potential Role in Rheumatic Disease

Cytokine	Size (kD)	Receptors	Major Cell Sources	Selected Functions
TNF	26 (pro)	TNF-RI (p55)	Monocytes; T, B, NK cells; PMNs; eosinophils; mast cells; fibroblasts; keratinocytes; glial cells; osteoblasts; smooth muscle	Monocyte activation, cytokine, and PG \uparrow
		TNF-RII (p75)		PMN priming, apoptosis, oxidative burst \uparrow Endothelial cell adhesion molecule, cytokine release \uparrow ; fibroblast proliferation and collagen synthesis \downarrow MMP and cytokine \uparrow T cell apoptosis; clonal (auto)regulation; TCR dysfunction Adipocyte FFA release \uparrow Endocrine effects—ACTH, prolactin \uparrow ; TSH, FSH, GH \downarrow Peripheral lymphoid development
LT α	22-26	TNF-RI	T cells; monocytes; fibroblasts; astrocytes; myeloma; endothelial cells; epithelial cells	
RANK ligand	35	TNF-RII RANK	Stromal cells; osteoblasts; T cells	Otherwise similar bioactivities to TNF Stimulates bone resorption via osteoclast maturation and activation Modulation of T cell-DC interaction
OPG	55	RANKL	Stromal cells, osteoblasts	Soluble decoy receptor for RANKL
BlyS \dagger	18-32	TACI BCMA BlyS-R	Monocytes; T cells; DCs	B cell proliferation, Ig secretion, isotype switching, survival
APRIL	—	TACI BCMA	Monocytes; T cells; tumor cells	T cell co-stimulation B cell proliferation Tumor proliferation

*Additional members of importance include TRAIL, TWEAK, CD70, FasL, and CD40L. At least 18 members of the family are now described.

\dagger Also called BAFF.

ACTH, adrenocorticotropic hormone; APRIL, a proliferation inducing ligand; BAFF, B cell activating factor belonging to the TNF family; BCMA, B cell maturation protein; BlyS, B lymphocyte stimulator protein; DC, dendritic cell; FFA, free fatty acid; GAG, glycosaminoglycan; LT, lymphotoxin; MMP, matrix metalloproteinase; NK, natural killer; OPG, osteoprotegerin; PG, peptidoglycan; PMN, polymorphonuclear neutrophil; RANK, receptor activator of NF κ B ligand; TACI, transmembrane activator and calcium modulator and cyclophilin ligand; TNF, tumor necrosis factor; TRAIL, TNF-related apoptosis-inducing ligand; TWEAK, TNF-like weak inducer of apoptosis.

Table 26-3 Cytokines Associated Predominantly with Effector Function for T Cells*

Cytokine	Size (kD)	Receptors	Major Cell Sources	Key Functions
Type II Interferon				
IFN- γ	20-25	IFN γ R	Th/c1 cells; NK cells; $\gamma\delta$ T cells; B cells; macrophage/DCs	Macrophage activation, DC APC function \uparrow Endothelial adhesion molecule \uparrow MHC class II expression \uparrow T cell growth \downarrow ; opposes Th2 responses Bone resorption \downarrow ; fibroblast collagen synthesis
4α-Helix Family				
IL-2	15	IL-2R α IL-2/15R β γ -chain	Th/c cells; NK cells	T cell division; maturation; cytokine release; cytotoxicity NK cell cytokine release; cytotoxicity; monocyte activation Lymphocyte apoptosis \downarrow Th2 differentiation, maturation, apoptosis \downarrow B cell maturation; isotype switch (IgE) Eosinophil migration, apoptosis \downarrow Endothelial activation; adhesion molecule expression
IL-4	20	IL-4R α / γ -chain IL-4R α /IL-13R1	Th/c cells (Th2); NK cells	B cell differentiation; immunoglobulin production (IgA) Eosinophil differentiation and activation Th/c maturation
IL-5	25 monomer 50 homodimer	IL-5R α IL-5R β	Th/c2 cells; NK cells; mast cells; epithelial cells	
IL-17 Family[†]				
IL-17A/F	20-30	IL-17R	T cells (Th17); fibroblasts	Chemokine release, fibroblast cytokine release, MMP release \uparrow Osteoclastogenesis; hematopoiesis Chondrocyte GAG synthesis \downarrow Leukocyte cytokine production \uparrow
IL-25 (IL-17E)	20-30	IL-17R	Th2 cells	Th2 cytokine release; B cell IgA and IgE synthesis; eosinophilia; epithelial cell hyperplasia

*Additional T cell–derived cytokines of potential interest include IL-13 from Th2 and NK2 cells.

[†]IL-17 family also contains IL-17B and IL-17C, the distinct functions of which are currently unclear.

APC, antigen presenting cell; DC, dendritic cell; GAG, glycosaminoglycan; IFN, interferon; MHC, major histocompatibility complex; MMP, matrix metallo-proteinase; NK, natural killer; Th/c, T helper/cytotoxic.

Table 26-4 Cytokines Described Initially with Primary Role in Regulation of T Cells*

Cytokine	Size	Receptors	Major Cell Sources	Key Functions
IL-12	IL-12/23p40 IL-12p35	IL-12R α IL-12R β 1 IL-12R β 2	Macrophages; DCs	Th1 cell proliferation, maturation T cell cytotoxicity B cell activation
IL-15	15 kD	IL-15R α IL-2/15R β γ -chain	Monocytes; fibroblast; mast cells; B cells; PMNs; DCs	T cell chemokinesis, activation, memory maintenance NK cell maturation, activation, cytotoxicity Macrophage activation, suppression (dose dependent) PMN activation, adhesion molecule, oxidative burst Fibroblast activation B cell differentiation and isotype switching B cell activation
IL-21	15 kD	IL-21R γ -chain	Activated T cells; others (?)	Th17 cell expansion and activation; IL-17 release
IL-23	IL-12/23p40 IL-23p19	IL-23R IL-12R β 1	Macrophages; DCs	

*Cytokines included in this table are now understood to exhibit considerable functional heterogeneity as shown. Other T cell regulatory cytokines have been described including IL-27, the functions of which are currently under investigation.

DC, dendritic cells; NK, natural killer; PMN, polymorphonuclear neutrophil.

Table 26-5 IL-10 Superfamily Cytokines*

Cytokine	Receptors	Cellular Sources	Key Functions
IL-10	IL-10R1	Monocytes; T cells; B cells; DCs; epithelial cells; keratinocytes	Macrophage cytokine release, iNOS, ROI ↓; soluble receptor ↑
	IL-10R2		T cell cytokine release, MHC expression ↓; anergy induction Treg cell maturation; effector function (?) DC activation, cytokine release ↓ Fibroblast MMP, collagen release ↓; no effect on TIMP B cell isotype switching enhanced
IL-19	IL-20R1/IL-20R2	Monocytes; others (?)	Monocyte cytokine and ROI release; monocyte apoptosis
IL-20	IL-22R/IL-20R2	Keratinocytes; others (?)	Autocrine keratinocyte growth regulation
IL-22	IL-22R/IL-10R2	Th17 cells; CD8 T cells; γδ T cells; NK cells	Acute-phase response, keratinocyte activation proliferation ↑
IL-24	IL-22R/IL-20R2 IL-20R1/IL-20R2	Monocytes; T cells	Tumor apoptosis; Th1 cytokine release by PBMC

*Additional members include IL-26, IL-28, and IL-28A. Many functions of IL-10 superfamily are as yet poorly understood, but they likely reside beyond the immune system.

DC, dendritic cell; iNOS, inducible nitric oxide synthase; MMP, matrix metalloproteinase; NK, natural killer; PBMC, peripheral blood mononuclear cells; ROI, reactive oxygen intermediates; TIMP, tissue inhibitor of metalloproteinase.

Table 26-6 IL-6 Superfamily Cytokines*

Cytokine	Size (kD)	Receptors	Major Cell Sources	Key Functions
IL-6	21-28	IL-6R† gp130	Monocytes; fibroblasts; B cells; T cells	B cell proliferation; immunoglobulin production Hematopoiesis, thrombopoiesis T cell proliferation, differentiation, cytotoxicity Hepatic acute-phase response Hypothalamic-pituitary-adrenal axis Variable effects on cytokine release by monocytes
Oncostatin M	28	OMR gp130	Monocytes; activated T cells	Megakaryocyte differentiation Fibroblast, TIMP, and cytokine release Acute-phase reactants, fibroblast protease inhibitors ↑ Monocyte TNF release ↓; IL-1 effector function ↓ Hypothalamic-pituitary axis ↑; corticosteroid release Modulatory effect on osteoblast (?) Proinflammatory effects in some models (?)
Leukemia inhibitory factor	58	LIFR gp130	Fibroblasts; monocytes; lymphocytes; mesangial cells; smooth muscle cells; epithelial cells; mast cells	Acute-phase reactants ↑ Hematopoiesis, thrombopoiesis Role in neural development, neural effector function, implantation Bone metabolism; extracellular matrix regulation Leukocyte adhesion molecule expression Eosinophil priming Mixed proinflammatory versus anti-inflammatory effects in models

*Additional members of potential importance include IL-11, cardiotropin-1, and ciliary neurotrophic factor. Note overlapping effects within family.

†Membrane or soluble form can dimerize gp130 to promote signaling, which promotes signal transduction.

LIFR, leukemia inhibitory factor receptor; OMR, oncostatin M receptor; TIMP, tissue inhibitor of metalloproteinase; TNF, tumor necrosis factor.

Table 26-7 Growth Factors Relevant to Rheumatic Diseases

Cytokine	Receptors	Cellular Sources	Key Functions
TGF- β^*	Type I TGF β R	Broad—including fibroblasts, monocytes, T cells, platelets	Wound repair, matrix maintenance, and fibrosis
Isoforms 1-3†	Type II TGF β R		Initial activation then suppression of inflammatory responses
	Others		T cell (Treg and Th17) and NK cell proliferation and effector function ↓ Early-phase leukocyte chemoattractant, gelatinase, and integrin expression ↑ Early macrophage activation then suppression, reduced iNOS expression
BMP family (BMP2-15)	BMPRI	Varied (e.g., epithelial and mesenchymal embryonic tissues); bone-derived cell lineages	Regulate critical chemotaxis, mitosis, and differentiation processes during chondrogenesis and osteogenesis, tissue morphogenesis (e.g., heart, skin, eye)
PDGF	BMPRII PDGFR α	Platelets; macrophages; endothelial cells; fibroblasts; glial cells; astrocytes; myoblasts; smooth muscle cells	Local paracrine or autocrine growth factor for variety of lineages
FGF family	PDGFR β FGFR (various) Basic FGF Acidic FGF	Widespread	Wound healing Growth and differentiation of mesenchymal, epithelial, and neuroectodermal cells

*Members of TGF- β superfamily include BMP, growth and differentiation factor, inhibinA, inhibinB, müllerian inhibitory substance, glial-derived neurotrophic factor, and macrophage inhibitory cytokine.

†Bound to latency-associated peptide to form small latency complex and to latent TGF- β binding protein to form large latent complex; activated by proteolytic and nonproteolytic pathways.

BMP, bone morphogenetic protein; FGF, fibroblast growth factor; iNOS, inducible nitric oxide synthase; NK, natural killer; PDGF, platelet-derived growth factor; TGF, transforming growth factor.

Table 26-8 Miscellaneous Cytokines with Potential Roles in Rheumatic Diseases

Cytokine	Size (kD)	Receptors	Cellular Sources	Key Functions
MIF	12	Unclear	Macrophages; activated T cells; fibroblasts (synoviocytes)	Macrophage cytokine release, phagocytosis, NO release ↑ T cell activation; DTH Fibroblast proliferation; COX expression; PLA ₂ expression Intrinsic oxidoreductase activity ("cytozyme")
HMGB1	30	RAGE, dsDNA Others (?)	Widespread expression; necrotic cells; macrophages; pituicytes	DNA-binding transcription factor Necrosis-induced inflammation Macrophage activation—delayed proinflammatory cytokine Smooth muscle chemotaxis Disrupts epithelial barrier function Bactericidal (direct)
GM-CSF	14-35	GM-CSFR α GM-CSFR β	T cells; macrophages; endothelial cells; fibroblasts	Granulocyte and monocyte maturation; hemopoietic effects Leukocyte PG release; DC maturation Pulmonary surfactant turnover
G-CSF	19	G-CSFR	Monocytes; PMNs; endothelial cells; fibroblasts; various tumor cells; stromal cells	Granulocyte maturation; promotes PMN function
M-CSF	28-44	M-CSFR	Monocytes; fibroblasts; endothelial cells	Monocyte activation, maturation
IL-32 α - δ	Unknown	Unknown	Monocytes; T cells; NK cells; epithelial cells	Promotes proinflammatory cytokine release from variety of cells
Type I interferons IFN α/β family	Various	IFN $\alpha\beta$ R	Widespread	Antiviral response Broad immunomodulatory effects (promotes MHC expression) Macrophage activation; lymphocyte activation and survival Antiproliferative, cytoskeletal alteration, differentiation ↑

COX, cyclooxygenase; DC, dendritic cell; DTH, delayed-type hypersensitivity; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HMGB, high mobility group box chromosomal protein; IFN, interferon; M-CSF, macrophage colony-stimulating factor; MIF, macrophage inhibitory factor; NO, nitric oxide; PG, prostaglandin; PLA, phospholipase A; PMN, polymorphonuclear neutrophil; RAGE, receptor for advanced glycation end products.

cytokine control transiently contribute to organized functional subunits—such as the ectopic germinal center, synovial lining layer, or renal interstitial nephritis—yet remain competent to migrate thereafter under the influence of chemotactic gradients on the extracellular matrix. Cytokines also may promote cell death (apoptosis) either by withdrawal (e.g., IL-2, IL-7, IL-15) or by binding cytokine receptors containing death domains (e.g., TNF-R1). Cytokines contribute at every stage of inflammatory lesion development in a dynamic equilibrium, rather than in a static, linear manner. Chronic inflammation in rheumatic disease usually contains cytokine activities reminiscent of innate and acquired immune responses. For convenience, cytokines can be considered by their effect on cell subsets and cellular interactions (Figure 26-2 describes a notional positioning for cytokine activity in a developing and chronic lesion). Investigation of cytokine-regulated pathways in several rheumatic diseases has identified numerous common pathways.

T Cell Effector Function in Chronic Inflammation

T cells depend on cytokine function at every developmental stage from bone marrow stem cell maturation, through thymic education, to functional determination and maturation after primary or secondary antigen exposure (see detailed overview in Chapter 13). The latter is of prime importance because re-education of phenotypic T cell responses may be achieved through alteration of the ambient cytokine milieu. T cell receptor–peptide–major histocompatibility complex (MHC) interactions during T cell–dendritic cell interaction rely on co-stimulatory molecule and local cytokine expression to determine functional outcome (see Tables 26-3 and 26-4). IL-12, in the presence of IL-18, promotes type 1 phenotypic development, characterized ultimately by IFN- γ -producing T helper type 1 (Th1) effector cells.²⁰ IFN- γ drives macrophage priming and activation and adhesion molecule expression and promotes granuloma formation and microbial killing. IFN- γ has a complex role in tissue destruction, however, with contradictory data obtained in inflammation models in IFN- γ -deficient and IFN- γ receptor-deficient mice. IFN- γ ultimately may retard tissue destruction, perhaps by suppressing osteoclast activation.²¹

A novel T cell subset has been defined that secretes IL-17A predominantly (Th17 effector cells), together with IL-22. Th17 cells are generated in the presence of IL-6 and transforming growth factor (TGF)- β , expanded by IL-1 β and IL-23, and antagonized by IL-25 (IL-17E) and paradoxically by IFN- γ . IL-17A provides a direct and rapid route to tissue damage via such means as osteoclast activation or FLS activation.²² The precise contribution of Th17 cells in human autoimmune disease is currently unclear. There are, however, persuasive data from rodent models indicating that Th17 cells may be of primary importance as initiator and effector cells. Clinical trials that target IL-17A are ongoing in various rheumatic diseases.

IL-4 dominance during T cell–dendritic cell interactions in the presence of IL-18 leads to type 2 responses, which promote humoral immunity driven by Th2 cells synthesizing primarily IL-4, IL-5, IL-10, and IL-13. Resulting pathogenesis more likely may be B cell mediated. Cytokines that

predispose to regulatory T cell development are unclear, although high levels of IL-10 or TGF- β have been suggested in this context.²³ Effector T cells can operate via secretion of cytokines to patterns determined by their prior activatory conditions.

Cell-to-Cell Interactions

In many inflammatory lesions, there is relative paucity of inducer T cell–derived cytokines (especially IL-17A or IFN- γ), despite abundant proinflammatory cytokine expression. Cell-cell membrane interactions between leukocyte subsets and between tissue cells and leukocytes have emerged as a dominant mechanism sustaining chronic inflammation. Cytokines contribute to these interactions at several levels (see Figure 26-3) including directly as membrane-expressed ligands, indirectly via activating cells, and synergistically by enhancing their subsequent cognate activities. The importance of cytokine-cell contact interactions is best studied in synovial tissues but applies to many inflammatory lesions. Many data now show that cognate interactions between T cells and adjacent macrophages constitute a major pathway driving cytokine release and that cytokines sustain this pathway (see Figure 26-3). Such interactions do not depend on T cell receptor–mediated T cell activation and provide a route to expansion of inflammation by T cells independent of local autoantigen recognition.

Vey and colleagues²⁴ first observed monocyte activation via cell contact with mitogen-stimulated T cells. Freshly isolated synovial T cells activate macrophages by this mechanism, confirming that contact-induced cellular activation is a fundamental property of inflammatory T cells.²⁵ Antigen-independent, cytokine-mediated bystander activation confers this capacity on human CD4⁺ memory T cells.²⁶ Studies using synovial T cells from rheumatoid arthritis and psoriatic arthritis tissues reveal that exposure of memory T cells to synergistic combinations of cytokines are most potent in this respect, particularly IL-15, TNF, and IL-6.^{27,28} Cytokine activities also operate directly on macrophages to synergize with T cell contact. IFN- γ and IL-18 are most potent in this respect, acting via increased adhesion molecule expression.

Activated memory CD4⁺ and CD8⁺ T cells promote cytokine release from macrophages via diverse membrane ligands including LFA-1/ICAM-1, CD69, and CD40/CD154.^{27,29} After contact with T cells, macrophages release increased concentrations of TNF and IL-1, but not IL-10, and they exhibit reduced levels of IL-1Ra. Th1 cells promote relatively greater proinflammatory cytokine release than do Th2 cells after co-culture. This finding suggests that their functional phenotype extends beyond cytokine secretion to include a differential membrane receptor array.³⁰ This suggestion is borne out further in the relative phenotypic distinctions between Th1 (CD40L, CCR5, IL-18R α) and Th2 (IL-33R/ST2, CXCR3) cells. The role of Th17 cells in this context is unknown. Signaling pathways engaged in monocytes after such T cell–membrane interactions are distinct from the pathways activated by conventional cytokine-inducing agents. Distinct use of phosphatidylinositol 3-kinase, NF κ B, and p38 mitogen-activated protein kinase pathways is observed.³¹ Similarly, discrete macrophage signals follow contact with

cytokine-activated T cells (which resemble synovial T cells) compared with T cell receptor-activated T cells.³² Such distinctions offer therapeutic potential in targeting cytokine-activated, T cell-driven pathways, leaving antigen-driven responses relatively intact. The activation state of memory T cells necessary for the previously discussed interactions to proceed remains controversial. Purified resting T cell subsets activate synovial fibroblasts to release IL-6, IL-8, matrix metalloproteinase 3 (MMP3), and prostanoids, in synergy with IL-17.³³

It is likely that T cells are activated by interactions with diverse moieties including extracellular matrix components and potentially autoantigens. Nevertheless, it is now clear that cytokines can promote chronicity by activating T cells to promote inflammation regardless of local (auto)antigen recognition and that this has enormous therapeutic potential (see Figure 26-3).

Agonist/Antagonist Cytokine Activities in Chronic Inflammation

Complex regulatory interactions exist to suppress ongoing inflammatory responses. This is often achieved via parallel secretion of antagonistic cytokines and soluble receptors to regulate cytokine effector pathways. Th1 responses are suppressed partly by cytokines of Th2 type (e.g., IL-4, IL-10), and consequently exaggerated Th1 responses arise in models in which the Th2 response is deficient.²⁰ Th1 and Th2 cells similarly limit Th17 cell expansion.²² Similar regulatory loops operate for other leukocytes, exemplified by the yin-yang effects of TNF and IL-10 on macrophage cytokine release and effector function.³⁴

Inhibitory cytokine activities are usually defined with respect to a proinflammatory cytokine, and in other contexts they may have quite distinct function, rendering prediction of their net contribution to an inflammatory response difficult. IL-10 opposes many of the proinflammatory effects of TNF and IL-1 β (e.g., reduces adhesion molecule expression, MHC expression, and MMP release), but it potently activates B cell activation and immunoglobulin secretion.³⁴ Similarly, TNF, which is normally considered a proinflammatory moiety, may have an important role in regulating T cell function because T cells removed from sites of chronic inflammation exhibit suppressed capacity to signal via their T cell receptor that recovers on TNF neutralization.³⁵ Such regulation is complicated further by the precise ratio of cytokine to soluble receptor such as TNF to sTNFR or IL-10 to sIL-10R within the local environment. Commensurate with this, administration of anti-inflammatory cytokines such as IL-4, IL-10, and IL-11 has generally proved disappointing in the context of clinical inflammatory diseases. Suppressed IL-10 production might be one unanticipated effect of p38 MAP kinase inhibitors, with efficacy of these agents and underscoring the importance of considering the complex interplay between proinflammatory and anti-inflammatory cytokines. An important caveat is the potential requirement of combinations of cytokines to suppress inflammation optimally (e.g., combinations including IL-4, IL-10, and IL-11). Further functional antagonism is exemplified in the antagonistic activities of IL-1 β and IL-1Ra and of IL-18 and IL-18 binding protein in regulating macrophage activation.

The role of cytokines in regulating cognate interactions between leukocytes has emerged more recently. Although anti-inflammatory pathways are poorly induced after cell contact, cytokine-activated T cells can induce IL-10 release by monocytes.³² Rheumatoid arthritis synovial membrane IL-10 release, which is partially T cell dependent, feeds back to regulate TNF release. Cytokine production from adjacent cell lineages within an inflammatory lesion may also be suppressive. IFN- β reduces mitogen-activated, T cell-induced macrophage release of TNF and IL-1, whereas IL-1Ra release is enhanced.³⁶ This provides a mechanism whereby type I IFNs could modify proinflammatory cytokine production. Regulation extends beyond conventional cytokine activities. Prostaglandins and lipoprotein moieties, particularly high-density lipoprotein, can suppress cytokine-mediated, T cell-macrophage interactions.³⁷

Disease-Modifying Antirheumatic Drugs

Conventional disease-modifying antirheumatic drugs can also act via modulation of cytokine production. Methotrexate modulates release of various cytokines *in vitro*, in part mediated via the adenosine-cyclic adenosine monophosphate pathway.³⁸ The active metabolite of the dihydroorotate dehydrogenase inhibitor leflunomide, A77 11726, reduces TNF, IL-1 β , IL-6, and MMP-1, but it does not reduce IL-1Ra release by monocytes after mitogen-activated T cell contact.^{39,40} Leflunomide may mediate these activities through modulation of inhibitor of NF κ B (I κ B) α phosphorylation and degradation and AP-1 and c-Jun N-terminal protein kinase activation.⁴¹ Sulfasalazine is an inhibitor of proinflammatory cytokine-induced NF κ B. Biologic agents also potently modify cytokine expression in a variety of disease states. Signal transduction inhibitors such as agents that inhibit JAK and Syk not only inhibit cytokine action but also the subsequent production of additional cytokines that can exacerbate disease.

Cellular Interactions across Diverse Tissues

Cytokines promote cognate cellular interactions across a range of tissues. In contrast to T cell-macrophage and T cell-dendritic cell interactions, in which adhesion molecule and co-stimulatory pathways are often implicated, cell-cell membrane communications apart from leukocyte-leukocyte interactions are often mediated through membrane cytokine expression (see Figure 26-3). T cell contact-mediated activation of fibroblasts operates via membrane TNF and IFN- γ to enhance fibroblast cytokine release and MMP—but not tissue inhibitors of metalloproteinase—expression, favoring tissue destruction.²⁹ The source and activation status of the fibroblast are vital; fibroblast-like synoviocytes, but not cutaneous fibroblasts, are potently activated by this route. Other studies have shown T cell contact-mediated activation of neutrophils, keratinocytes, mesangial cells (via a combination of membrane cytokine and CD40L expression), platelets, and renal tubule epithelial cells. Cytokine-activated macrophages (via IFN- γ and sCD40L) may interact via cell contact with mesangial cells to activate adhesion molecule and chemokine release by the latter. Cell-cell contact between cells of the immune system and beyond likely represents a ubiquitous mechanism whereby

perpetuation of chronic inflammation is potently influenced by local production of cytokines.

B Cells and Cytokine Release in Chronic Inflammation

Cytokines are crucial to B cell maturation, proliferation, activation, isotype switching, and survival (see Chapter 14). Cytokine-mediated B cell activation is important in immune complex generation, B cell antigen presentation, B cell–T cell interactions, and germinal center formation. Particular importance has been placed on the TNF superfamily cytokines, BLyS and APRIL. These cytokines are crucial for B cell development, survival, and optimal activation. Their hierarchical place is, however, now disputed at least in terms of RA biology because clinical targeting of both using atacicept (which neutralizes both BLyS and APRIL) has proven inefficacious in RA. Neutralization of BLyS with a monoclonal antibody has been similarly disappointing in RA, although more promising data have emerged in the treatment of SLE. B cells in turn represent a potent source of cytokines such as IL-6 and IL-10. B cells also have been considered important inducers of macrophage-derived cytokine release. This process may operate primarily via immune complex formation⁴² or through regulation of T cell activation (with B cell help). Complex regulatory feedback loops involving cytokine expression and B cells are likely important in a range of rheumatic diseases in which B cells are of paramount pathophysiologic importance. This may be one core mechanism whereby B cell depleting strategies in rheumatic diseases (e.g., via use of rituximab) are mediating their effects.

Innate Cell Lineages in Chronic Inflammation

Cytokines potently activate innate response cells that contribute to the chronic inflammatory lesion of a variety of rheumatic diseases. Tables 26-1 through 26-8 document relevant examples in which neutrophils, natural killer cells, eosinophils, and mast cells may be recruited and activated by the presence of appropriate cytokine combinations.

Growth Factors in Chronic Inflammation

Many data document the importance of growth factor families in chronic inflammation. TGF- β superfamily members including TGF- β isoforms and bone morphogenetic protein family members warrant particular reference. TGF- β is critically involved in processes of cell proliferation, differentiation, inflammation, and wound healing.⁴³ Bone morphogenetic proteins, in addition to regulating inflammatory responses, are paramount in determining cartilage and bone tissue development and remodeling.⁴⁴ As such, they are of increasing interest in the pathogenesis of several rheumatic diseases.

CYTOKINE EFFECTS BEYOND IMMUNE REGULATION

A striking feature of the cytokine field concerns the broad functional pleiotropy exemplified in the effects of cytokines in normal physiologic and adaptive processes. Cytokine

activities are found in muscle, adipose tissue, central nervous system, and liver, mediating normal regulation of metabolic pathways and modulation imposed by altered tissue conditions. Examples are found not only in the release of adipokines that regulate adipose metabolic pathways but also in the release of conventional cytokines by fat pads in inflammatory synovitis. Because cytokines thereby likely mediate normal and pathophysiologic activities in many tissues, it is increasingly recognized that they may underlie the comorbidity that is observed in vascular, central nervous system and bone tissues in several rheumatic diseases. Thus cytokines or their receptors arising from the primary target tissues (e.g., joint, kidney) may “leak” into the circulation and promote excess pathology in other tissues. Commensurate with this targeting, such cytokines may modulate this co-morbid risk. This is now exemplified in the reduction of vascular morbidity in patients receiving TNFi.

SUMMARY

Cytokines represent a diverse family of glycoproteins active across a broad range of tissues. Their pleiotropic functions and propensity for synergistic interactions and functional redundancy render them intriguing therapeutic targets. So far, single cytokine targeting has proved useful in several rheumatic disease states. Further elucidation of the biology and functional interactions within this expanding family of bioactive moieties is likely to prove informative in resolving pathogenesis and in generating novel therapeutic options.

KEY POINTS

Cells die in different ways with the morphologic appearance of apoptosis, autophagy, or necrosis.

Apoptosis proceeds through defined biochemical pathways that are initiated through death receptors on the cell surface or by intracellular signals emanating from damaged organelles.

Phagocytes recognize alterations on the surface of dead and dying cells signaling them to engulf the intact apoptotic cell or necrotic cell debris.

Different types of cell death dictate different immune responses.

Defects in apoptosis and defective clearance of dead and dying cells lead to immune responses to self (autoimmunity).

Many anti-inflammatory and immunomodulatory agents, as well as biologics affect cell survival pathways and offer new opportunities for therapeutic intervention.

HISTORY AND CONCEPTS

Apoptosis

Illustrations of cells undergoing apoptosis were made almost as soon as stains were used to examine the appearance of cells in different tissues. Drawings of ovarian follicles undergoing cell death made over 100 years ago demonstrate cell shrinkage and nuclear condensation. Subsequent descriptions of “pyknosis,” chromatin margination, and other terms used to convey the appearance of subcellular particles during cell death included many features now recognized as apoptosis. The history of this subject is reviewed elsewhere.¹

Our modern understanding of apoptosis began with electron microscopic descriptions of morphologic changes characterized by shrinkage of hepatocytes (i.e., *shrinkage necrosis*) after ischemic or toxic injury to the liver. The name *apoptosis* was coined by Kerr, Wyllie, and Currie in 1972 to describe the form of death that was “consistent with an active, inherently controlled phenomenon” characterized by cell shrinkage, nuclear condensation, and cell blebbing (Figure 27-1).² This term also conveyed the concept of cell death that was similar to leaves falling from a tree (*apo* means “from,” and *ptosis*, “a fall,” in Greek), implying a regulated “mechanism of cell deletion, which is complementary to mitosis.”²

Cell Survival and Death in Rheumatic Diseases

KEITH B. ELKON

Further developments in apoptosis paralleled advances in molecular biology, genetics, and biochemistry. The detection of a nucleosomal ladder³ was of considerable importance, because it defined a biochemical event (i.e., nucleosomal cleavage) and provided a simple electrophoretic test for detection of apoptotic cell death that remains a standard in the field (see [Laboratory Detection of Apoptosis](#) later in this chapter). Another landmark was the discovery in the 1980s that the death of cells during development of the nematode *Caenorhabditis elegans* was under strict genetic control. Remarkably, the death of these cells could be perturbed by mutations of a small number of genes called *ced* (for cell death abnormal) genes.⁴ Horvitz and colleagues determined that two *ced* genes, *ced3* and *ced4*, encoded death effectors, whereas *ced9* was an antiapoptotic gene.⁴ Most of the remaining *ced* genes were responsible for engulfment and removal of “corpses.” This simple model in which CED-3 is the main death protease that is activated by CED-4 and inhibited by CED-9 has served as a paradigm for defining apoptotic pathways in mammalian cells (Figure 27-2). In 2002, Robert Horvitz was awarded the Nobel Prize for discoveries concerning the genetic regulation of programmed cell death.

Mammalian cells are much more complex and, as will be discussed in detail, have multiple defined pathways that follow the basic *C. elegans* model. The molecules within these pathways, the downstream effectors of apoptosis, the caspases (cysteine aspartate proteases), and the proteins implicated in the clearance of apoptotic cells are discussed in detail here. Regulation of cell death is of seminal importance in a number of diseases, including cancers, autoimmune diseases, and degenerative disorders.^{5,6} The relevance of apoptosis to rheumatic disorders is summarized at the end of the chapter.

Programmed Cell Death

Whereas *apoptosis* originally referred to the appearance of dying cells in certain contexts, as explained earlier, the concepts of atrophy, cellular or tissue involution or regression, and degeneration had been appreciated for hundreds of years, yet the two phenomena were not associated until relatively recently. Perhaps the most precise descriptions of cells that died in an orderly and apparently programmed fashion were documented in developmental biology. Examples included the involution of cells between digits, the metamorphosis of insect larvae, and the death of specific cells during development of *C. elegans*.

Figure 27-1 Electron microscopic morphology of cell death. **A**, A cytotoxic T cell (lower left) conjugated to its target, P815 (a murine mast cell), before initiation of cell death. **B**, Induction of apoptotic changes in P815. Note the reduction in target cell size, the nuclear condensation, and the vacuoles with relative preservation of organelles. **C**, Osmotic lysis and necrosis in P815 induced by antibody and complement. Note the increased size of the nucleus and the apparently random fragmentation of the chromatin. Organelles are severely disrupted. **C**, dense chromatin; **M**, mitochondria; **P**, nuclear pore; **V**, vacuoles. **D**, Electron microscopic appearance of autophagy. An autophagosome (AP) is observed in a normal rat kidney cell. The autophagosome is surrounded by two cisterns of rough endoplasmic reticulum (ER). A Golgi stack (Go) is visible next to the autophagosome. (**C**, Adapted from Russell JH, Masakowski V, Rucinsky T, et al: *Mechanisms of immune lysis III: characterization of the nature and kinetics of the cytotoxic T lymphocyte induced nuclear lesion in the target*, J Immunol 128:2087, 1982, with permission. **D**, Figure kindly provided by Eeva-Liisa Eskelinen, Department of Biosciences, Helsinki, Finland.)

Figure 27-2 *Caenorhabditis elegans* paradigm of apoptosis. Genes involved in the regulation, execution, and clearance of apoptotic cells during development of *C. elegans* and their mammalian homologues are shown. In this figure, only the most closely related homologues are indicated, but as described in the text and shown in the figures, the complexity in mammalian cells is much greater. Note that at least half of the cell death abnormal (CED) proteins are involved in engulfment and removal of apoptotic corpses. Two distinct but partially overlapping pathways of engulfment are present in *C. elegans*: CED-2, -12, -5, and -10, which most likely regulate cytoskeletal changes, and CED-1 and -6, which may be involved in recognition (CED-1) and upstream signal transduction (CED-6). CED-7 is homologous to the mammalian adenosine triphosphate (ATP)-binding cassette transporter-1 (ABC-1), which likely affects membrane dynamics. The lower right panel shows a schematic of the two proposed pathways for apoptotic cell ingestion in mammalian cells. In pathway (1), an unknown receptor(s) triggers activation of the GTPase, RhoG, which leads to transport of the scaffolding protein, ELMO, to the cell membrane. There, Dock 180, a guanine exchange factor, promotes Rac activation, leading to activation of the cytoskeleton and phagocytosis. In pathway (2), activation of the CED-1 homologue (most likely CD91) interacts with the adapter protein, GULP, and downstream activation of the cytoskeleton.

Autophagy

Autophagy, which means “to eat oneself,” is essentially a protective process that occurs after growth factor withdrawal or nutrient depletion that may or may not result in cell death. The process is highly conserved from yeast through humans. Under circumstances of nutrient depletion, cells switch to a catabolic program in which cellular constituents are degraded for energy production as a survival mechanism. In these cells, a double membrane vesicle (autophagosome) forms around organelles or protein aggregates and encapsulates them (see [Figure 27-1D](#)). A characteristic feature of this process is the lipidation of LC3 (microtubule-associated protein 1 light chain 3) to form LC3-II, which can be identified as coarse dots on the autophagosomes seen by microscopy (see [Figure 27-6I](#), later), or by changes in molecular mass on Western blot analysis. The autophagosomes then fuse with the lysosomes, leading to degradation of their contents ([Figure 27-3](#)).

The biochemical pathways by which autophagy is initiated and executed are complex and are schematically outlined in [Figure 27-3](#). In brief, lack of nutrients leads to a reduction in phosphoinositide (PI)-3 kinase activity, resulting in loss of suppression of mTOR (mammalian target of rapamycin) and activation of autophagic (ATG) proteins. The ATG gene family comprises at least 20 members and includes beclin1 (ATG6), a protein that is critically involved in the regulation of autophagic cell death.⁷ Beclin1 is monoallelically deleted in a variety of human cancers, and may function in control of cell growth and in tumor suppression.⁸ Autophagic death shares a number of morphologic features with necrotic cell death⁹ and may be seen in neuronal cell death associated with polyglutamine repeats. Many reports indicate that autophagy is important in immune function. Examples include intracellular host response to pathogens, survival of lymphocytes after growth factor withdrawal, Toll-like receptor (TLR) stimulation in plasmacytoid dendritic cells (pDCs), and major histocompatibility complex (MHC) class II presentation of antigen.^{10,11} The strongest link between autophagy and autoimmunity or autoinflammatory disease is the association between a genetic variant of ATG16L1 and another protein that regulates autophagy, the immunity-related guanosine triphosphatase gene (IRGM), and Crohn's disease. The precise mechanisms that account for this association remain to be determined.¹¹

Necrosis

Necrosis (from the Greek *nekros*, meaning “corpse”) is distinguished from apoptosis predominantly by morphologic appearance.¹² Necrotic cells are swollen, and electron microscopy reveals disorderly fragmentation of chromatin and severe damage to the mitochondria (see [Figure 27-1](#)). The cellular membrane loses integrity and becomes permeable to vital dyes such as trypan blue and propidium iodide (see [Figure 27-6](#), later). The distinction between apoptosis and necrosis remains important from a number of perspectives. In contrast to the genetic and biochemical programs that regulate apoptosis, necrotic cells usually result from death “by accident,” that is, from thermal or drug injury, infection, or infarction of an organ. Because of uncontrolled release of intracellular contents, necrotic cells induce a pro-inflammatory immune response, whereas apoptotic cells usually elicit an anti-inflammatory response.

The same inducers (e.g., ischemia, hydrogen peroxide) may produce apoptosis or necrosis, depending on the severity of the injury and the rapidity of cell death. The fate of the cell is determined in part by cellular energy reserves, especially adenosine triphosphate (ATP).¹³ ATP is generated by oxidative phosphorylation in mitochondria, as well as by glycolysis in the cytosol. Some inducers initially may cause apoptosis followed by necrosis (postapoptotic necrosis). This is likely to occur when removal of apoptotic cells is delayed and is thought to be important in stimulating an inflammatory response to self-antigens. A unique type of necrosis in neutrophils, called **NETosis**, is implicated in SLE^{13a} (see Defective Uptake and Processing of Apoptotic Cells).

Pyroptosis

Pyroptosis (from the Greek *pyro*, meaning “fire”) is distinguished from other forms of cell death first and foremost by the activation of caspase 1 (interleukin [IL]-1 β -converting enzyme) and secretion of the inflammatory cytokine, IL-1 β . Pyroptosis is most strongly associated with infection by intracellular bacteria such as *Salmonella*, *Yersinia*, and *Legionella*, although it may also be seen following tissue infarction.¹⁴ Cells undergoing pyroptosis demonstrate nuclear condensation associated with DNA damage, cell swelling, and ultimately cell lysis associated with release of IL-1 β .¹⁴ The mechanisms responsible for this process involve intracellular sensors of bacterial products and formation of the

Figure 27-3 Pathways of autophagy (ATG). Autophagy is initiated by starvation or by activation of intracellular immune sensors. ATG proteins are activated, leading to the nucleation of an isolation membrane (green rectangle) and conjugation of phosphatidylethanolamine to LC3. Continued concerted activities of ATG proteins lead to formation of the autophagosome from the isolation membrane, which then fuses with lysosomes to form autolysosomes. The contents of the autolysosomes are degraded, and the products recycled for energy utilization.

inflammasome. These topics are briefly described in the following sections and elsewhere in the text (see Chapter 18).

BIOCHEMISTRY OF APOPTOSIS

A schematic diagram of the cell death program is shown in Figure 27-4. A brief outline of each major functional component within the program, from signals for death to removal of apoptotic cells, is provided here, but space limitations preclude a detailed analysis of the layers of regulation at each step of the pathway. For example, post-translational protein modifications such as phosphorylation, nitrosylation, and oxidation present additional complexities that are under intense study. A series of reviews in *Apoptosis and Its Relevance to Autoimmunity*¹⁵ offer more detailed information on the biochemistry of apoptotic pathways and their relationship to immune function.

The specialized proteins involved in apoptosis and its regulation contain a number of modules or domains that are predominantly involved in promoting protein-protein interactions (Table 27-1). These domains may be found

Table 27-1 Modular Components of Proteins Involved in Apoptosis and Inflammation

Module*	Component of	Function
BH (1-4)	Bcl-2 family	P-P-I
BIR	IAP family	P-P-I
CARD	Caspases, adapters, NODs	P-P-I
DD	Death receptors, adapters, kinases	P-P-I
DED	Adapters, caspases	P-P-I
LRR	Pyrin family, NODs, TLR	P-P-I
NBS/NOD	Pyrin family, NODs	Nucleotide-binding, oligomerization
Pyrin	Pyrin family	P-P-I
RING finger	IAP family	E3-ubiquitin ligase

*See Mariathasan and Monack¹⁸⁰ for further discussion.

BH, Bcl-2 homology; BIR, baculovirus AIP repeat; CARD, caspase recruitment domain; DD, death domain; DED, death effector domain; IAP, inhibitor of apoptosis; LRRs, leucine-rich repeats; NBS, nucleotide-binding site; NOD, nucleotide oligomerization domain; P-P-I, protein-protein interaction; TLR, Toll-like receptor.

Figure 27-4 Mammalian apoptotic pathways. Cell death can be initiated by multiple pathways, including an extrinsic ligand-induced pathway (left), an intrinsic pathway mediated by the mitochondria (middle), and an intrinsic pathway mediated through the endoplasmic reticulum (ER) (right). Examples of stimuli that can induce each of these pathways are shown and are discussed in further detail in the text. Note that these pathways differ in the upstream caspases activated but converge to cleave the effector caspases, such as caspase 3, during execution of apoptosis. Tumor necrosis factor receptor (TNFR) and other “death receptors” can also signal cell survival by activation of nuclear factor kappa B (NFκB). During ER stress, unfolded proteins release the ER chaperone protein, Bip, from binding to the stress sensor proteins, IRE, PERK, and ATF6. PERK attenuates protein synthesis, whereas ATF6 and JNK are transcription factors that upregulate the expression of proapoptotic proteins that contain UPR elements such as CHOP (GADD 153) and caspases. In mice, caspase 12 is the initiator caspase, whereas in human cells, caspases 4 and 7 have been implicated. Alterations that occur during dissolution of the cell are too numerous to mention, but a few are highlighted in view of their potential relevance to autoimmunity (see text). Exposure of phosphatidylserine (PS) on the cell surface (lower left area) provides a simple means of detection of apoptotic cells through binding of annexin V and may be relevant to the generation of antiphospholipid autoantibodies and coagulation disorders in vivo. Cleavage products of chromatin (lower middle area), as well as proteins, such as lamins and DNA-PK, may be antigenic. AIF, apoptosis inducing factor; CAD, caspase-activated DNase; Cyt c, cytochrome-c; DD, death domain; DED, death effector domain.

in receptors, adapters, effectors, or inhibitors. Furthermore, as will be discussed later, these domains occur in proteins involved in apoptosis, as well as inflammation (Supplemental Figure 27-1 on www.expertconsult.com). It has been suggested that death domain (DD), death effector domain (DED), caspase recruitment domain (CARD), and pyrin domain all evolved from the prototypic DD-fold, corresponding to an antiparallel six-helix bundle.¹⁶ In general, like domains bind so as to facilitate homotypic interactions, leading to oligomerization of the same protein or binding to different proteins in a signaling pathway. These changes usually produce conformational alterations, which lead to further protein recruitment. Other domains such as the nucleotide-binding site (NBS) specify nucleotide binding.

DEATH LIGANDS, RECEPTORS, AND SIGNALS

Death of a cell may result from intracellular stress activating an intrinsic death program, or it may be forced on the cell by the interaction of a death ligand with a death receptor (see Figure 27-4). Death receptors (DRs) belong to the tumor necrosis factor (TNF) receptor (TNFR) superfamily of proteins, which comprises approximately 25 members.^{17,18} This family of receptors is responsible for diverse biologic responses such as inflammation, proliferation, antiviral activity, and cell death. Receptors in the TNF family include at least six receptors capable of transmitting apoptosis (see later), as well as receptors such as CD40, CD30, BlyS/BAFF/TALL, and TACI,¹⁷ which trigger survival and/or proliferation in part through activation of nuclear factor κ B (NF κ B). Although most receptors of the TNFR family exert their effects primarily within the immune system, some members (e.g., p75NGFR, TNFR I and II) appear to serve important functions in the nervous system and in other organs. Some TNFR-like proteins, such as PV-T2, PV-A53R, and CAR1, are encoded by viruses and may contribute to their virulence.¹⁷

Death Receptors

The DRs identified, including Fas, TNFR I, DR-3 (TRAMP/wsl/APO-3), DR4 (TRAIL, receptor for the Apo2 ligand), DR5, and DR6, share homology in their intracellular domains over a 70 amino acid region called the *death domain* (DD).¹⁹ Three decoy receptors have been identified—two (DcR1 and DcR2) that bind and inhibit their ligand, TRAIL, and one (DcR3) that binds Fas ligand. These decoy receptors presumably modulate the cytotoxic function of the ligands, but their biologic contexts remain to be fully defined. Use of alternative splice forms and shedding of the receptors and ligands also downmodulate their function.

TNFR family members are characterized by two to six cysteine-rich domains (CRDs) in their extracellular regions.¹⁷ The co-crystal structure of TNFR I and lymphotoxin- α indicates that CRDs project from the cell surface in a linear array, making distinct contact with ligands at subunit interfaces. The first CRD may also be responsible for preassembly of the receptor as trimers that

undergo further conformational alteration upon ligand engagement.

The three-dimensional structure of the DD has been solved by nuclear magnetic resonance spectroscopy and has been shown to consist of six amphipathic α -helices that create a unique fold.²⁰ Functionally, the DD appears to be a novel protein-protein association motif that facilitates homotypic interactions. For example, the DD of Fas and TNFR I self-associate, thereby recruiting adapter proteins that also contain DD and that directly or indirectly mediate receptor signal transduction (see Figure 27-4).

Death Receptor Signal Transduction

This section will focus predominantly on signaling from Fas and TNFR, because these are the best-characterized members of the death receptor subfamily, and it is likely that other death receptors signal through similar pathways. As illustrated in Figure 27-4, Fas and TNFR I share a common death pathway. Binding of Fas ligand to Fas causes conformational changes in the receptor cluster, leading to recruitment of intracellular adapter molecules. Initially, aggregation of Fas induces uptake of the adapter protein, FADD, to the DD of Fas. FADD has two structural domains: a C-terminal DD, which mediates Fas binding, and an N-terminal death effector domain (DED). The FADD DED allows recruitment of procaspase 8 and procaspase 10 through DED-DED interactions. Procaspases 8 and 10 have a bipartite structure comprising a DED and an enzymatic caspase domain, the latter linking Fas aggregation with the execution phase of apoptosis. Apposition of procaspases 8 and 10 to the activated Fas complex leads to autocatalytic cleavage and conversion of the proenzymes to activated proteases, which are released and are able to initiate a proteolytic cascade, leading to programmed cell death. In some cell lines, caspase 8 cleavage also results in cleavage of the proapoptotic molecule Bid, which activates the mitochondrial amplification cascade (type II pathway²¹; Supplemental Figure 27-2 on www.expertconsult.com; see also Figure 27-4).

Although the six DD-containing receptors initiate cell death in certain contexts, all may signal cell survival/proliferation in different cell types and/or in different contexts. The ability to signal an opposite cell fate depends on the recruitment of proteins such as tumor necrosis factor receptor-associated factors (TRAFs), which activate NF κ B, thereby promoting cell survival (see later).

Defective function of caspase 8 leads to a form of cell death called **NECROPTOSIS** that combines features of apoptosis and necrosis resulting in activation of NF κ B and production of inflammatory cytokines such as TNF.^{21a}

Death Ligands

FasL (CD178) is a 40-kD type II transmembrane protein that shares 15% to 35% amino acid identity with the TNF superfamily of ligands. FasL is expressed constitutively in the anterior chamber of the eye and in the testis but is induced when CD8, T helper-1 (Th1) CD4⁺ T cell, and some natural killer (NK) cell populations become activated.²² In lymphocytes, expression of ligand is tightly regulated and activity on the cell surface short-lived, because

Supplemental Figure 27-1 Components of inflammasomes. Inflammasomes contain pro-interleukin (IL)-1 but different sensors and regulators. In most cases, two stimuli (e.g., activation of a Toll-like receptor [TLR] or nucleotide-binding oligomerization domain [NOD] sensor plus potassium flux) are required to activate the inflammasome.⁵¹ The prototypic inflammasome containing caspase 1 or 5 (caspase 11 or 12 in mice) and the adapter protein, ASC (Pycard), is shown. A NALP3-containing inflammasome is of rheumatologic interest because it is activated by uric acid and certain nucleic acids. NOD2 is mutated in Crohn's disease and Blau syndrome. Pyrin is mutated in familial Mediterranean fever (FMF). The domain structure of these proteins (see Table 27-1) is as follows: a = CARD domain; b = nucleotide-binding site; c = leucine-rich repeat; d = pyrin domain.

excessive, if unfolded proteins persist, or if post-translational protein modification is abnormal.³⁷ Apoptosis is the result of three central players: inositol-requiring protein-1 (IRE1), activating transcription factor-6 (ATF6), and protein kinase RNA-like ER kinase (PERK) (see [Figure 27-4](#)). Unfolded proteins may activate these proteins directly, or by binding to the ER chaperone immunoglobulin-binding protein, Bip. Once activated, the three proteins cause selective RNA cleavage, termination of protein synthesis, and induction of proapoptotic responses (see [Figure 27-4](#)). In contrast to the death receptor or mitochondrial pathways, apoptosis is executed through caspase 12 in mice and possibly caspase 4 in mammals.³⁸ However, many of the same molecules that regulate apoptosis in the mitochondria, the Bcl-2 family in particular, also influence ER-mediated apoptosis, possibly through control of intraluminal calcium. It is important to point out that induction of the UPR, in certain circumstances, leads to NFκB activation and inflammation, rather than cell death.³⁹

Antiapoptotic Proteins: FLIP, Bcl-2, IAPs, and Akt

(See [Supplemental Figure 27-2](#) on www.expertconsult.com.)

Cellular homeostasis within each tissue is carefully regulated. Excessive cell growth or premature cell death translates into disease, as will be discussed in the last part of this chapter. The death and survival pathways are finely balanced, and each cell death program is regulated, often at multiple levels. Before we discuss how the death program is executed, we will describe the way in which cell death is modulated by inhibitors of apoptosis.

Inhibition of Death Receptors

In most resting cell types that express Fas on their cell surface (e.g., lymphocytes), the receptor is nonfunctional. Resistance to death is explained both by low levels of expression of the receptor and by active inhibition by a protein called FLIP. FLIP resembles the structure of caspase 8 and competes with caspase 8 for recruitment to FADD. This prevents FADD from initiating apoptosis. When lymphocytes become activated, FLIP is usually degraded, allowing Fas signal transduction to occur unimpeded (see [Supplemental Figure 27-2](#) on www.expertconsult.com). Similarly, a protein called SODD (silencer of death domain) attenuates TNFR I signal transduction.

Bcl-2 Family of Cell Death Regulators

The Bcl family comprises more than 18 members.⁴⁰ Bcl-2 is the prototype antiapoptotic protein that was first discovered to be overexpressed in certain B cell lymphomas (Bcl). Of particular significance, Bcl-2 overexpression did not enhance cell proliferation (most cells were in the G₀/G₁ phase of the cell cycle) but rendered the cells more resistant to death. The antiapoptotic members—Bcl-2, Bcl-XL, Bcl-w, Mcl-1, and A1—contain three or four of the characteristic Bcl-2 homology (BH) domain motifs and most possess the N-terminal BH4 domain and the hydrophobic C-terminal membrane anchor, accounting for their

attachment to mitochondrial, ER, and nuclear membranes (see [Supplemental Figure 27-2](#) on www.expertconsult.com). Virus-encoded proteins—BHRF1, LMW5-HL, ORF16, KS-Bcl-2, and E1B-19K—and Bcl-2 have similar antiapoptotic functional properties. The proapoptotic members of this family can be subdivided into two groups: the Bax/Bak-like proteins (Bax, Bak, Bok, and BCL-Xs), which contain two to three BH3 domains, and the BH3-only subset (Bad, Bik, Bid, Hrk, Bim, Noxa, Puma, and Bmf), which contain only the single domain. Bcls are regulated at transcriptional and post-transcriptional levels by a multitude of stimuli.

How do Bcls regulate apoptosis? One level of regulation is conferred by binding interactions (homodimerization or heterodimerization) between members via their BH1, BH2, and BH3 domains.⁴¹ Although outcomes vary for each specific pair, homodimerization of Bcl-2 or Bax potentiates their antiapoptotic or proapoptotic functions, respectively, whereas heterodimers may potentiate or abrogate function of one member of the pair. Bax and Bak have been shown to be pivotal downstream effectors of intrinsic apoptotic pathways. A possible model is that Bcl-2 (or homologues) usually heterodimerizes with Bax and Bak, preventing apoptosis. Increased expression of a BH3 proapoptotic protein causes binding to Bcl-2, thereby releasing Bax and Bak to induce apoptosis. It has also been suggested that BH3 proteins may bind and directly activate Bax/Bak.

Bcl regulation of cell death is closely connected to mitochondrial function. The physical association of Bcl-2 family proteins with the outer mitochondrial membrane, as well as the close structural similarity between BH1 and BH2 domains and bacterial pore-forming proteins such as colicin,⁴² allows them to regulate ion fluxes or the transfer of small molecules from the membrane. In vitro models suggest that Bax and Bak promote opening of the VDAC, allowing the release of cytochrome-c into the cytosol, whereas Bcl-2 binds directly to VDAC and closes it.³⁴

Intracellular Inhibitors of Apoptosis (IAPs)

Intracellular inhibitors of apoptosis (IAPs) are a separate family of antiapoptotic proteins that are highly conserved through evolution. The neuronal apoptosis inhibitory protein (NAIP) was discovered through association of NAIP mutations in patients with the severe form of spinal muscular atrophy. Seven additional members of the family (c-IAP-1, -2, X-IAP, survivin, ILP2, ML-IAP, and Bruce) that share a baculovirus IAP repeat (BIR) domain have subsequently been identified; most contain a RING domain that functions as an E3 ligase. Ubiquitylation may target interacting proteins for proteasomal degradation, or they may be activated. IAPs such as X-IAP directly inhibit effector caspases, especially caspase 9 (see [Supplemental Figure 27-2](#) on www.expertconsult.com), whereas cIAPs modulate cell survival through ubiquitylation of substrates such as RIP and proteins in the NFκB pathway (see [Supplemental Figure 27-2](#) on www.expertconsult.com).⁴³ IAPs block apoptosis induced by a variety of stimuli, including Fas, TNF, ultraviolet irradiation, and serum withdrawal, and survivin is overexpressed in certain cancers and in the rheumatoid arthritis (RA) synovium.⁴⁴ In some cells, the antiapoptotic effect of IAPs is eliminated by release of the protein Smac/

Supplemental Figure 27-2 Inhibitors of apoptosis. Inhibitors of death pathways are shown in *brown*. Note that a number of tumor necrosis factor (TNF) family members (e.g., CD40L, BAFF/ BLYS/TALL, receptor activator of NF κ B [RANK] ligand) activate the nuclear factor κ B (NF κ B) pathway, resulting in increased transcription of antiapoptotic proteins, inhibitors of apoptosis (IAPs), Bcl-2 family members, and A1.¹⁸¹ In some cases, inhibitors of apoptosis are blocked or destroyed during apoptosis. For example, the protein Smac/Diablo is released from mitochondria and eliminates the antiapoptotic effect of the IAP family. Growth factors impart survival signals, in part through the phosphoinositide (PI)-3 kinase → Akt pathway (*right side of diagram*). Activation of the kinase, Akt, directly inactivates certain proapoptotic proteins such as Bad and caspase 9, and promotes survival by inhibiting the forkhead family (FKRL) of transcription factors and enhancing the expression of the antiapoptotic protein, NF κ B.¹⁸² Inhibitor of caspase-activated DNase (ICAD) is a specific inhibitor of the DNase, CAD, which is degraded by caspases. Tetrapeptide inhibitors of specific caspases are shown in *blue*.

metalloproteases cleave the extracellular portion of the ligand into soluble, functional molecules. The zinc metalloprotease, TNF-converting enzyme (TACE), is a membrane-anchored member of the disintegrin family of proteases that cleave active TNF from the cell surface.^{23,24}

Function in Immune Regulation

Although Fas and FasL interactions in the thymus are not thought to play a major role in negative selection, this pathway is involved in the maintenance of immune privilege in the eye and the testis, in the pathogenesis of graft-versus-host disease, and in immune evasion by tumor.²² The major physiologic function of Fas and FasL in the immune system is the preservation of peripheral tolerance. This is achieved by the phenomenon of activation-induced cell death (AICD), whereby CD8 T cells, Th1 CD4⁺ T cells, and possibly NK cells induce apoptosis of activated T cells, B cells, and macrophages. Deletion of activated immune cells removes the source of proinflammatory molecules, prevents the continued presentation of self-peptides by primed (high levels of co-stimulatory molecules) antigen-presenting cells, and eliminates B cells that have mutated to self-specificity within the germinal centers.²⁵ More recently, it has been shown that Fas-FasL interactions promote a variety of additional functions, including early T cell proliferation, tumor survival, and cell migration. These topics are discussed in greater detail elsewhere,^{26,27} and the consequences of Fas deficiency are described later in this chapter.

It should be noted that, whereas TRAIL signals apoptosis through DR4 and DR5 predominantly in tumor cells, evidence suggests that TRAIL also plays a role in negative selection of thymocytes.²⁸ Similarly, DR3 (TWEAK, receptor for the Apo3 ligand) has been implicated in negative selection.²⁹ Finally, DR6 plays a role in immunologic homeostasis, as evidenced by enhanced T and B cell proliferation in DR6-deficient mice.³⁰

INTRINSIC CELL DEATH PATHWAYS: INITIATION AND EXECUTION OF APOPTOSIS

Cells need constant sources of nutrition and depend on a variety of signals for active maintenance of survival. Loss of signals from neighboring cells³¹ or withdrawal of growth factors or cytokines results in initiation of a cell death program. Damage or stress to intracellular organelles may be induced from outside or within the cell. Here, injury or stress to DNA, mitochondria, and the endoplasmic reticulum is discussed.

Genotoxic Injury

Mutations occur frequently in mammalian DNA and usually are promptly repaired. However, if repair fails or DNA is severely damaged by radiation or drugs, the transcription factor, p53 ("guardian of the genome"), is upregulated and phosphorylated by DNA damage sensors such as ATR and ATM. Activated p53 induces cell cycle arrest through induction of the cyclin-dependent kinase inhibitor, p21. If

DNA damage is repaired, cell cycle arrest is abrogated, whereas if the injury cannot be repaired, the cell undergoes apoptosis. The critical importance of p53 as a tumor suppressor is illustrated by the high frequency of p53 mutations in cancers.³² p53 induces apoptosis, in part through transcription of death effectors such as Bax that cause mitochondrial stress. In addition, activation of the transcription factor Foxo-1 upregulates the expression of Bim, FasL, and TRAIL.³³

Mitochondrial Stress

Mitochondria are cytoplasmic organelles that contain their own 16-kb genome encased by inner and outer membranes, with a number of proteins, including cytochrome-*c*, situated between these membranes (see Figure 27-4). Mitochondria help to maintain redox potential and serve as the energy powerhouse of the cell through the generation of ATP by oxidative phosphorylation. These biochemical pathways create an electrochemical gradient ($\Delta\psi$) that is positive and acidic on the outside and alkaline on the inner side of the mitochondrial membrane. Spanning the inner membrane is the adenine nuclear translocator (ANT), which mediates ATP transport (with VDAC, see later) to the cytosol. On the outer mitochondrial membrane (OMM) is situated the voltage-dependent anion channel (VDAC), which is permeable to solutes of approximately 5000 kD.³⁴

Genotoxic injury, reduced supply of nutritional or growth factors, raised intracellular calcium, reactive oxygen intermediates (ROIs), and exposure to certain chemicals such as staurosporine cause mitochondrial stress. These initiating factors lead to selective mitochondrial membrane permeabilization (MMP) with resulting dissipation of the proton gradient responsible for the $\Delta\psi$ permeability transition, permeabilization of the outer membrane, and loss of ATP production. Mitochondria themselves are the major producers of ROIs, which, in excess, damage nucleic acids, proteins, and membrane lipids.

Once MMP is initiated, cytochrome-*c* is released from the intermitochondrial space into the cytosol (see Figure 27-4). In the cytosol, cytochrome-*c* and the cofactors Apaf-1 and ATP or dATP assemble with caspase 9 to form a molecular aggregate called the *apoptosome*, which promotes the cleavage of procaspase 9 into its active form.³⁵ Caspase 9 acts on effector caspases such as caspase 3, resulting in the caspase cascade that leads to cleavage and inactivation of a wide variety of substrates within the cell (see Figure 27-4). A caspase-independent apoptosis-inducing factor (AIF) is also released from the mitochondria and induces nuclear changes and cell death by less well defined pathways.³⁶

Endoplasmic Reticulum (ER) Stress

The main functions of the ER are to regulate intracellular calcium flux and to promote proper folding of nascent proteins. In the contiguous conduit, the Golgi apparatus, post-translation modifications such as glycosylation and isoprenylation are executed. Elaborate mechanisms are in place to ensure that errors in protein folding do not occur, but if they do, an unfolded protein response (UPR) is initiated. The ER/Golgi initiates apoptosis if calcium flux is

Diablo or Omni/HtrA2 from the mitochondria (see [Supplemental Figure 27-2](#) on www.expertconsult.com).

Akt

Akt is a cytosolic protein kinase (protein kinase B) that serves a special role in prevention of apoptosis, because it links cell activation through PI-3 kinase with multiple transcription factors. Phosphorylation of Akt is antagonized by the phosphatase, PTEN. When phosphorylated, Akt promotes cell survival by altering the function of intrinsic (mitochondrial) and extrinsic (death receptor) pathways of apoptosis. Specifically, this includes inactivation of proapoptotic molecules such as caspase 9 and Bad, and activation of survival pathways that include NF κ B and forkhead transcription factors that inhibit FasL (see [Supplemental Figure 27-2](#) on www.expertconsult.com).⁴⁵ Antiapoptotic molecules may be cell type or context specific.

CASPASES

Caspases are cysteine-containing proteases that have an unusual substrate specificity for peptidyl sequences with a P1 aspartate residue.^{46,47} These proteases are 30 to 50 kD in size and comprise an amino-terminal prodomain with a large subunit domain and a small subunit domain (see [Figure 27-4](#)). Active site cysteine residue is contained within the conserved pentapeptide, QACxG, on the large subunit of the enzyme, whereas most of the substrate specificity is determined by the small subunit. The upstream caspases 8, 9, 10, 2, and 4 have large prodomains that interact with regulatory proteins such as FADD for caspases 8 and 10 and Apaf-1 for caspase 9 (see [Figure 27-4](#)). Clustering of these complexes allows autocatalytic cleavage of large and small subdomains to form the active tetramer. Effector caspases such as 3, 6, and 7 have small prodomains and are thought to be cleaved into their active forms by the upstream caspases.

Members of the caspase family can be divided into three functional subgroups on the basis of their substrate specificities.⁴⁸ Group I members (caspases 1, 4, and 5) are potently inhibited by the serpin CrmA; group II members (caspases 2, 3, and 7) are specific for DExD; and group III members (caspases 6, 8, 9, and 10) are specific for I/V/LExD—a sequence that is also contained at the junctions of the caspase subunits themselves. Significantly, granzyme B produced by cytotoxic T cells has a substrate specificity similar to that of group III caspases and is capable of inducing apoptosis through this pathway. Identification of the substrate specificity of caspases has led to a number of practical applications, including the ability to quantify activity using fluorogenic tetrapeptide substrates and blockade of proteolytic activity with noncleavable cell-permeable tetrapeptide analogues (see [Supplemental Figure 27-2](#) on www.expertconsult.com).

Effector caspases are necessary for the execution of apoptosis. They cleave specific substrates such as the structural proteins fodrin, gelsolin, and lamins, which are key intracellular enzymes involved in DNA repair (e.g., poly ADP ribose polymerase, DNA-PK) (see [Figures 27-4 and 27-6](#) [later]). These changes facilitate inactivation of synthetic

functions of the cell, dissolution of the nuclear membrane, and packaging of cellular proteins into apoptotic blebs on the cell surface. Caspases also cleave regulatory proteins such as Bcl family members and the inhibitor of caspase-activated DNase (ICAD). Cleavage of ICAD leads to the release of active CAD, which enters the nucleus and cleaves nucleosomes at the linker region, yielding the characteristic “DNA ladder” (see [Figures 27-4 and 27-6](#) [later]).^{49,50}

As was already mentioned in the section on pyroptosis, not all caspases are involved in the execution of apoptosis. Human caspases 1, 4, 5, and 12 and mouse caspases 1, 4, 11, and 12 are most likely involved in inflammation. Caspase 1 and caspase 5 interact to form a multiprotein complex that has been called the *inflammasome*⁵¹ (analogous to binding of the apoptosome caspases 1 and 5 to the adapter proteins, ASC [PYCARD] and NALP1 [DECAP], respectively, by their CARD domains) (see [Supplemental Figure 27-1](#) on www.expertconsult.com). ASC and NALP1 are multidomain proteins that contain many of the protein interaction domains listed in [Table 27-1](#). The N-terminus of the protein, pyrin, which is mutated in familial Mediterranean fever (FMF), binds to ASC. The C-terminus of pyrin, which is mutated in FMF, binds directly to IL-1 β , suggesting that pyrin normally directly exerts an inhibitory effect on IL-1 β .⁵²

Caspases are tightly regulated by their own prodomains and by Bcl and IAP family members (see [Supplemental Figure 27-2](#) on www.expertconsult.com). In addition, viral proteins such as serpin CrmA, produced by cowpox, and p35, produced by baculovirus, are potent inhibitors of caspases.

FINDING, REMOVING, AND RESPONDING TO DEAD AND DYING CELLS

Finding the Dying Cell

During apoptosis, the enzyme, calcium-independent phospholipase A2, is activated by caspase cleavage, leading to the generation of lysophosphatidylcholine (LPC) (see [Figure 27-5](#) for complete apoptosis schema). LPC acts both as a soluble chemoattractant for macrophages and as an epitope on the cell membrane for natural immunoglobulin (Ig)M antibodies.⁵³ Additional “find-me” signals include sphingosine-1-phosphate (S1P) and the nucleotides ATP and UTP, which are released by dying cells, especially as the plasma membrane becomes damaged (necrosis).^{54,55} Intravital microscopy coupled with biochemical studies revealed that cell necrosis led to release of ATP, activation of Nrlp3 inflammasomes, and release of IL-1 β .⁵⁶ Subsequently, a chemokine gradient attracted neutrophils to the site of cell damage and formylated peptides to the necrotic cell.

Eating the Dying Cell

Of the 14 *C. elegans* death genes (*ced1* through *ced14*), at least half encode proteins that are required for engulfment of apoptotic cells (see [Figure 27-2](#)).⁵⁷ CED-7 is present in the membrane of both the apoptotic cell and the phagocyte, whereas remaining proteins function in the phagocyte to execute two partially overlapping pathways of engulfment.

Figure 27-5 **A**, Attraction and keep-out signals released by dying cells. Lactoferrin is a keep-out signal for neutrophils. LPC, lysophosphatidylcholine; S1P, sphingosine-1-phosphate. **B**, Receptors, ligands, and opsonins (bridging proteins) implicated in recognition or phagocytosis of apoptotic cells (see text for details). CRP, C-reactive protein; CRT, calreticulin; LyPtC, lysophosphatidylcholine; Ox, oxidized form; PS, phosphatidylserine; TSP, thrombospondin. Yellow circles are lipids or oxidized lipids.

CED-1 is a receptor that recognizes changes in the apoptotic cell and signals through CED-6 to activate the phagocyte. CED-2, -5, -10, and -12 most likely form a functional complex that activates Rac, which then promotes the cytoskeletal changes required to engulf the apoptotic prey.⁵⁸ The mammalian counterparts are described in Figure 27-2, and their signaling pathways are discussed in detail elsewhere.⁵⁹

Within the immune system alone, more than 10^9 apoptotic cells are removed from the body each day. These apoptotic cells are generated in vast numbers in central lymphoid organs such as the thymus and bone marrow by out-of-frame rearrangements of antigen receptors, negative selection, or simple “neglect.” A significant load of apoptotic cells is produced in the peripheral immune system because of the relatively short life span of myeloid cells and lymphocytes, as well as secondary selection of high-affinity B cells in germinal centers. Specialized sites of selection (i.e., thymus, bone marrow, and lymphoid follicles) have remarkably efficient phagocytes that rapidly remove the dying cells.

In contrast to live cells, which express cell surface proteins such as CD47 that prevent engulfment (“don’t eat me” signals), changes on dying cells promote their ingestion by phagocytes (“eat me” signals). Chief among these on early apoptotic cells is the appearance of phosphatidylserine (PS) on the cell surface membrane (see Figure 27-5). This membrane asymmetry (PS is usually located on the inner surface of the membrane) is caused by reduced function of a translocase and possibly by activation of a lipid scramblase.⁶⁰ PS acts as a ligand for receptors such as T cell immunoglobulin and mucin domain-containing molecule 4 (TIM-4) on dendritic cells and brain-specific angiogenesis inhibitor 1 (BAI1). Oxidation of PS or phosphatidylcholine promotes engagement by the scavenger receptor, CD36. In addition, PS is recognized by a number of serum opsonins such as annexin I, Gas6, beta-2 glycoprotein 1 β_2 -glycoprotein 1, and milk fat globule epidermal growth factor 8 (MFG-E8). This diverse group of proteins allows the apoptotic cells to

bind to different receptors (see Figure 27-5). For example, MFG-E8 predominantly facilitates apoptotic cell clearance in germinal centers,⁶¹ whereas C1q deficiency leads to apoptotic cell accumulation in the kidney.⁶² As mentioned earlier, natural IgM antibodies and acute phase proteins such as C-reactive protein (CRP) bind to phosphorylcholine on the cell membranes of dying cells and amplify classic pathway complement deposition.^{63,64} Other serum opsonins or bridging molecules include thrombospondin, which bridges the $\alpha_v\beta_3$ and CD36 receptors,⁶⁵ and collectins (mannose-binding protein, C1q, and surfactant proteins). Collectin-binding receptors are controversial (see reference 66 for discussion). The ER protein, calreticulin, is unique in that it is translocated from the ER to the cell surface of apoptotic cells but can also be detected at low concentrations on live cells.⁶⁷

Despite the detection of only limited chemical alterations on the apoptotic cell membrane, blockade of a large and diverse number of receptors on phagocytes can impair the uptake of apoptotic cells (see Figure 27-5). This diversity is due to the heterogeneity of the opsonins, cell type selectivity, the context (homeostasis vs. inflammation), and partial redundant function of each individual receptor. All identified receptors have other functions, perhaps reflecting an evolution from receptors designed to remove apoptotic cells during development to pattern recognition receptors useful for host defense.⁶⁸ Many of the receptors are integrins comprising the vitronectin receptor, $\alpha_v\beta_3$,⁶⁹ $\alpha_v\beta_5$,⁷⁰ and complement receptors 3 (CD11b/CD18) and 4 (CD11c/CD18),⁷¹ as well as class A and B scavenger receptors. Non-integrin receptors include the PS-binding receptors, TIM-4 and BAI1 mentioned earlier, the ATP-binding cassette transporter (ABC1),⁷² CD14,⁷³ and the closely related Tyro 3 family receptor tyrosine kinases, c-Mer, TYRO, and Axl.⁷⁴ CD91 (LDL receptor-related protein) is a multifunctional receptor that recognizes 30 different ligands, of which calreticulin is one.⁶⁷ According to the “tether and tickle” model,⁷⁵ some receptors, such as CD14 or CR3, serve as

recognition structures and contribute to adhesion; others like CD91 convey signals for engulfment.

Responding to the Dying Cell

Ingestion of apoptotic cells has significant effects on the phagocyte and potentially on the T cell response to ingested antigens. *In vitro*^{76,77} and some *in vivo*⁷⁸ studies suggest that uptake of apoptotic cells by macrophages induces the expression of immunosuppressive cytokines such as transforming growth factor (TGF)- β 1, prostaglandin E₂, and possibly IL-10 by macrophages. These cytokines tend to dampen an immune response to self-antigens. Significantly, ligands for c-Mer, such as Gas6 and protein S on apoptotic cells, suppress production of IL-12, TNF, and interferon (IFN)- α by macrophages and/or dendritic cells. Apoptotic cells activate a specific transcriptional repressor of IL-12, GC-BP,⁷⁹ which also suppresses adaptive immune responses. Oxidized lipids derived from the apoptotic cell membranes activate two transcription factors—peroxisome proliferator-activated receptor δ (PPAR δ) and liver X receptor (LXR)—resulting in enhanced phagocytosis of apoptotic cells and suppression of inflammatory cytokines.⁸⁰ Because some peptides derived from apoptotic cells can be presented to lymphocytes by dendritic cells and possibly by macrophages through cross-priming,^{70,81} questions of critical importance for studies of autoimmunity include whether self-peptides are presented after phagocytosis of apoptotic cells, and under what conditions they induce tolerance or immunity.

Ligands (DAMPs) and Sensors for Cell Debris. Engulfment of dying cells is the first step of the “clean-up” process, but swift degradation of cellular contents both within the phagocyte and extracellularly is equally important. Recently, much attention has been devoted to the self-molecules that activate (called DAMPs for damage-associated molecular patterns, as opposed to PAMPs, which are pathogen-associated molecular patterns) and the sensors that respond to products from dead and dying cells (Supplemental Figure 27-3 on www.expertconsult.com). A partial list of DAMPs includes high mobility group B1 (HMGB1), nucleic acids, the nucleotides ATP and UTP, uric acid, heat shock proteins, and SAP130.⁸² SAP130 is a U2-associated spliceosome protein, although it is not known to be a common autoantigen. As shown in Supplemental Figure 27-3 on www.expertconsult.com, the sensors for DAMPs (e.g., TLRs, retinoic acid inducible gene I [RIG-I]-like receptors [RLRs]) are, for the most part, the same as those that sense PAMPs. Therefore, the concept that self/nonself-discrimination can be attributed to differences in sensors that are specific for self- versus foreign antigens is no longer tenable. Because self-molecules can stimulate inflammatory responses, it is vital that DAMPs be efficiently processed and rendered noninflammatory. Serum contains a potent DNase, DNase I, as well as abundant RNases that serve these functions. Opsonins such as CRP scavenge nucleoproteins for rapid removal.⁸³ Within the cell, a specific acid-activated DNase, DNase II, resides in lysosomes and degrades ingested nuclear DNA; multiple different endonucleases and exonucleases (see [Defective Uptake and Processing of Apoptotic Cells](#), later) have been described. As discussed later, failure to degrade these molecules or activation of the

inflammasome pathway likely explains why the debris from necrotic cells induces type 1 IFN, TNF, IL-1 β , and other proinflammatory cytokines (see earlier). Additional details on receptors and sensors for each molecule can be found in recent reviews.^{82,84}

LABORATORY DETECTION OF APOPTOSIS

Numerous methods have been devised to detect cells undergoing apoptosis. These methods depend on biochemical changes in the cell as described previously and are depicted in Figure 27-6. Electron microscopic examination (see Figure 27-1) is still regarded as the “gold standard.”

Cell Membrane Alterations

Annexin V binds to negatively charged phospholipids in a calcium-dependent manner and therefore can readily detect the flip of phosphatidylserine to the outer surface of the cell membrane (see Figure 27-6A). When annexin V is conjugated to fluorescein isothiocyanate (FITC), biotin, or other markers, it provides a convenient tag for detecting apoptotic cells by flow cytometry.⁸⁵ Flow cytometry detection with annexin V is simple and sensitive and detects cells at an early stage of apoptosis. Annexin V will also bind to necrotic cell membranes before complete rupture of the cell. Entry of trypan blue, as seen by light microscopy, or propidium iodide, as quantified by flow cytometry, into the cell indicates profound damage to the cell membrane indicative of necrosis. The fluorescent chemical, 7-amino-actinomycin D (7-AAD), intercalates into double-stranded nucleic acids but will enter the cell only after membrane damage, and therefore is also a useful marker of cell death by flow cytometry.

Loss of Mitochondrial Membrane Potential (MMP)

As was discussed previously, multiple stimuli lead to apoptosis through the intrinsic mitochondrial pathway, resulting in loss of membrane potential. Several dyes, including rhodamine 123, tetramethyl rhodamine methyl ester (TMRM) (see Figure 27-6B), and DiOC6, bind relatively selectively to mitochondria, thus providing a fairly sensitive measure of membrane potential.

Caspase Activation

As has been discussed, caspases are normally present in an inactive state, but once activated, they recognize specific tetrapeptide sequences (see Supplemental Figure 27-2 on www.expertconsult.com). Caspase activity therefore can be quantified directly in intact cells by flow cytometry analysis with cell-permeable fluorochrome tetrapeptide conjugates, or in cell extracts by enzyme-linked immunosorbent assay (ELISA) that detect release of colorimetric dyes conjugated to the tetrapeptides. Caspase activation can also be quantified indirectly by Western blot analysis of cleaved (activated) caspase 3, or of cleavage of specific caspase substrates.

Supplemental Figure 27-3 Sensors responsive to danger-associated molecular patterns. Sensors are shown as receptor structure, adapter proteins are shaded *blue*, and signaling pathways are abbreviated. Note that DNA may enter the cytoplasm from the nucleus, where exonucleases such as TREX1 degrade them. If this fails, a cytoplasmic sensor (possibly of the PYHIN type) stimulates the production of type 1 interferon. See text for details.

Figure 27-6 Methods of detection of apoptotic cells. A variety of methods are available for the identification and quantification of dying cells; a sampling is shown here. **A** through **C** depend on changes to the cell surface membrane, mitochondria, and caspase activation, whereas **D** through **H** detect changes in the nucleus. **A**, Apoptotic thymocytes were incubated with fluorescein isothiocyanate (FITC)-conjugated annexin V in the presence of the dye propidium iodide (PI), which permeates cells with severely damaged cell membranes. Note that cells in the *bottom left quadrant* (not stained for annexin or PI) are live, cells in the *lower right quadrant* are early apoptotic, and cells in the *upper right quadrant* are late apoptotic (stain with annexin and admit PI). For cells in suspension, such as lymphocytes, annexin V binding to phosphatidylserine (PS) is the most commonly used method to detect early apoptotic cells. **B**, Human embryonic kidney cells were incubated in medium alone (*upper panel*) or medium containing valinomycin, an ionophore that increases ionic permeability of the inner mitochondrial membrane (*lower panel*). The cells were then incubated with tetramethylrhodamine methyl ester (TMRM), a cell-permeable dye that binds to the outer mitochondrial membrane in proportion to its membrane potential ($\Delta\psi$), and were analyzed by flow cytometry. Note that the fluorescence intensity for the apoptotic cells is lower owing to loss of mitochondrial membrane potential (MMP). Other probes used in similar assays for mitochondrial potential are rhodamine 123 and the carbocyanine dye, DiOC6. **C**, Cells were induced to undergo apoptosis by anti-Fas antibodies. Cell extracts taken at 0, 4, and 6 hours post induction were analyzed for poly-ADP ribose polymerase (PARP) cleavage by Western blot analysis. Note that the 4- and 6-hour samples show partial cleavage of PARP (*arrow*). Western blot is also used for detection of activated caspase 3. **D**, Mouse peritoneal macrophages were incubated with apoptotic thymocytes, cytocentrifuged onto glass slides, and stained with Diff-Quik (Dade Behring, Deerfield, Ill). The *arrows* indicate ingested apoptotic cells with condensed nuclei. **E**, Thymocytes were induced to undergo apoptosis and then were incubated with macrophages. Cells were fixed and stained with the dye bisBENZIMIDE (Hoechst No. 33342; Hoechst AG, Frankfurt, Germany) and were viewed by immunofluorescence microscopy. All of the *dark blue circles* represent the nuclei of apoptotic thymocytes ingested by the macrophage, whereas the macrophage nucleus is the large less-dense circle marked by the *white arrowhead*. **F**, Normal (*left panel*) or apoptotic (*right panel*) cells were permeabilized and incubated with RNase, and their DNA stained with propidium iodide, according to the method of Nicoletti and colleagues.⁸⁶ The cells were analyzed by flow cytometry, and staining in the subdiploid peak (smaller than the G0/G1 peak and labeled M1 in the histogram) reflects the extent of apoptosis. **G**, Normal and apoptotic cells were lysed and the nuclei removed by centrifugation. Cytosolic extracts were then applied to agarose gels and components resolved by electrophoresis. Ethidium bromide staining of the extract made from live cells reveals high-molecular-weight DNA that remains close to the application well (*left lane*), whereas extract from apoptotic cells demonstrates loss of high-molecular-weight DNA and the appearance of the typical ladder of nucleosomes. **H**, Six-micron sections were made from a normal mouse thymus. The cells were permeabilized and incubated with biotinylated deoxyuridine triphosphate (dUTP) in the presence of terminal deoxynucleotidyl transferase (TdT). Nicked DNA incorporated the labeled deoxynucleotide and was detected by staining with peroxidase-labeled streptavidin and substrate (*dark color*). **I**, A breast cancer cell line was induced to undergo autophagy. Autophagic vesicles were detected with an anti-LC3 antibody by indirect immunofluorescence. (Figure kindly provided by Bassam Janji, Laboratory of Hemato-Oncology, Public Research Center for Health, Luxembourg, Belgium.)

Cleavage of the nuclear protein, poly-(ADP-ribose) polymerase (PARP), is also used to evaluate activation of caspase 3 (see Figure 27-6C).

Chromatin Condensation and DNA Fragmentation

Condensation of chromatin can be seen by light microscopy following nuclear staining (see Figure 27-6D). This can be a sensitive screening method depending on the experience of the viewer, but confirmation with a more specific assay is usually required for verification. Chromatin condensation is more easily seen by staining with vital dyes such as Hoechst No. 33342 bisBENZIMIDE (2'-[4-ethoxyphenyl]-5-[4-methyl-1-piperazinyl]-2,5'-bi-1H-benzimidazole) or DAPI (4',6-diamidino-2-phenylindole) (Hoechst AG, Frankfurt, Germany) and inspection under fluorescence microscopy (see Figure 27-6E). For precise quantification of nuclear condensation, DNA staining with propidium iodide and flow cytometry analysis of condensed (subdiploid) DNA are widely used (see Figure 27-6F).⁸⁶

As has been mentioned, DNA is cleaved by multiple DNases, leading to the cleavage of nucleosomes at the linker region between histone bindings, yielding the characteristic 180 base pair "DNA ladder" (see Figure 27-6G). DNA fragmentation results in free 3'-OH groups, which can be detected within the nuclei in tissue sections using biotinylated deoxyribonucleotide triphosphates (dNTPs) (terminal deoxynucleotidyl transferase 2'-deoxyuridine, 5'-triphosphate [dUTP] nick end-labeling [TUNEL] assay; see Figure 27-6H).⁸⁷ Whereas formation of the ladder is specific to apoptosis, generation of free ends of DNA is not, and may also be detected in DNA damaged by necrosis. Furthermore, it has been reported that TUNEL and in situ DNA incorporation methods may yield positive

results in cells undergoing extensive DNA repair or rapid proliferation.^{88,89}

Autophagy

As was discussed, during autophagy, lipidation of LC3 to form LC3-II can be identified as coarse dots on the autophagosomes by immunofluorescence microscopy. Figure 27-6I demonstrates such staining on a breast cancer cell line induced to undergo autophagic cell death.

APOPTOSIS IN RELATION TO RHEUMATIC DISORDERS

The regulation of apoptosis is highly relevant to the pathogenesis and treatment of rheumatic disorders. Pertinent examples are discussed in the following sections and are reviewed in Nagata et al.⁹⁰

Defective Apoptosis of Immune Cells

Mice with mutations of Fas or Fas ligand (FasL) develop a syndrome characterized by lymphoproliferation (*lpr*) and generalized lymphadenopathy (*gld*), together with systemic autoimmunity.⁹¹ As might be expected from the key role described for Fas in AICD, lymphadenopathy and splenomegaly are the consequences of failure of activated lymphocytes to die, resulting in an absolute increase in the numbers of T and B lymphocytes, as well as of the accumulation of an unusual subset of T cells that do not express CD4 or CD8 co-receptors (i.e., double-negative T cells). The nature and extent of systemic autoimmunity vary according to the strain into which the Fas or FasL mutation has been bred.⁹¹

A syndrome of massive lymphadenopathy with systemic autoimmunity in children was reported by Canale and Smith in 1967. Subsequently, these and other *lpr* patients were found to have mutations in Fas.⁹²⁻⁹⁴ The syndrome (called *Canale-Smith syndrome* [CSS] or *autoimmune lymphoproliferative syndrome* [ALPS]) is characterized by lymphadenopathy or splenomegaly, autoimmune cytopenias (most commonly affecting platelets and red cells), and an increase (>5%) in circulating double-negative T cells. Patients had defective lymphocyte apoptosis in response to anti-Fas antibodies or FasL when tested in vitro, and most had heterozygous mutations in Fas affecting the death domain. These mutations impair Fas-mediated apoptosis through a dominant negative effect.^{95,96} Although Fas/FasL mutations are an exceptionally rare contributory factor to systemic lupus erythematosus (SLE), ALPS is informative because it suggests that defective apoptosis of cells of the immune system can cause systemic autoimmune diseases such as idiopathic thrombocytopenic purpura, autoimmune hemolytic anemia, and Guillain-Barré syndrome. It illustrates (as do the mouse models) that even when a single gene has a powerful effect on predisposition to systemic autoimmunity, the clinical expression of disease depends on the precise nature of the mutation^{95,96} and the interaction with modifying genes. Recently, somatic mutations in Fas have been detected in cases where patients present at an older age and do not have germline mutations.⁹⁷

Several other examples of genetic alterations in death or survival genes may lead to lupus-like diseases in mice (reviewed in Kim et al⁹⁸). Of particular interest is overexpression of the ligand for the BlyS /BAFF receptor, which promotes the survival of B lymphocytes,⁹⁹ because increased expression of this ligand has been reported in SLE, Sjögren's syndrome, and rheumatoid arthritis.¹⁰⁰ Mutations in the p55/TNFR1/CD120a receptor in humans results in a periodic autoinflammatory syndrome called *tumor necrosis factor receptor-associated periodic syndrome* (TRAPS). Mutations predominantly occur in the first two CRDs of the receptor, resulting in reduced shedding of the extracellular domain of the receptor and reduced neutralization of circulating TNF.¹⁰¹ Increased lymphocyte survival due to overexpression of Bcl-2, knockout of Bim, reduction in PTEN activity,¹⁰² and increased survival of dendritic cells^{103,104} causes lupus-like autoimmunity in mice.

In summary, defective apoptosis of B or T cells may lead to inappropriate survival of self-reactive cells in the central (thymus or bone marrow) or peripheral immune system. Enhanced survival of dendritic cells may promote the activation and expansion of low affinity self-reactive T cells.

Defective Uptake and Processing of Apoptotic Cells

Autoantibodies were discovered in the 1940s and 1950s, and their molecular and functional identities were characterized in the 1980s and 1990s. Why the immune system targets a select subset of self-antigens (mainly nucleoproteins) in each disease has never been satisfactorily explained. The fact that autoantibodies target nucleosomes in SLE, while certain anticardiolipin antibodies cross-react with PS,

which translocates to the cell surface during apoptosis,¹⁰⁵ supports the idea that autoantibodies target the products of apoptotic cells. Additional inferential evidence for this hypothesis comes from detection of lupus antigens in apoptotic blebs,¹⁰⁶ modification of antigens by cleavage, and phosphorylation during apoptosis.^{107,108} Apoptotic blebs or microparticles may be released from dying cells; this has important consequences for immunoregulation.¹⁰⁹

Because apoptosis occurs on a vast scale in the central lymphoid organs and should tolerate the host, under what conditions would apoptotic cells immunize? If apoptosis occurs in the presence of an adjuvant agent (e.g., virus, bacterium, chemical agent), tolerance may be lost at least transiently. An interesting paradigm for the generation of the proinflammatory cytokine, IL-17, has been suggested in experimental animals in which TGF- β may be generated by apoptotic cells, together with IL-6 induced by certain microbes, thus promoting Th17 induction.¹¹⁰ Abnormalities leading to accelerated apoptosis of cells or reduced uptake of dying cells will allow cells to undergo postapoptotic necrosis; this, in turn, will provoke a proinflammatory cytokine response from phagocytes, as was explained previously. Indeed, an increase in the rate of apoptosis of SLE peripheral blood mononuclear cells has been observed,^{111,112} and it is suspected, but not proven, that ultraviolet exposure to the skin may induce excessive apoptosis in SLE patients. Reduced macrophage phagocytosis of apoptotic cells has been reported in SLE and increased apoptotic cell debris observed in germinal centers of lymph nodes obtained from SLE patients.^{113,114} This is of importance because B cells are positively selected in germinal centers, so an increase in self-antigen may enable selection of autoreactive B cells generated by somatic hypermutation.

It is well known that deficiencies of early complement components predispose to human SLE.¹¹⁵ Two overlapping explanations for this striking association are that phagocytosis of apoptotic cells is impaired in the absence of early complement components,^{62,71} and that C1q suppresses the induction of IFN- α by nucleoprotein-containing immune complexes.^{116,117} Knockout of members of the Tyro 3 receptor tyrosine kinases is associated with defective clearance of apoptotic cells and expression of a lupus-like disease,^{118,119} which may also be in part related to regulation of type I IFN.⁷⁴ Suh and associates¹²⁰ observed low levels of protein S, one of the ligands for the TAM receptors, in SLE patients.

Mammalian nucleic acids can potently stimulate TLR-dependent and -independent pathways to generate inflammatory cytokines. Deficiency of DNase I led to lupus, and conditional deficiency of DNase II caused an RA-like disease in mice.^{121,122} Failure to degrade DNA or DNA:RNA intermediates in the cytosol results in activation of type I IFN in the brain (humans—Aicardi-Goutières syndrome) or myocarditis in mice.¹²³ Approximately 2% of SLE patients have heterozygous mutations in TREX1.¹²⁴ Nucleic acids contained within immune complexes have been shown to stimulate IFN- α by plasmacytoid dendritic cells (pDCs), providing a plausible explanation for increased IFN- α observed in SLE and amplification of disease activity.¹²⁵ Some recent studies suggest that neutrophils may be a source of antigens, and that impaired degradation of neutrophil nets (neutrophil extrusions of DNA/histone complexes) may predispose to nephritis.¹²⁶

Prolonged Exposure to Growth Factors

Histologically, RA is characterized by an accumulation of inflammatory cells in the synovium, leading to pannus formation and destruction of cartilage and bone. Although Fas and FasL can be detected in RA synovium, and evidence of apoptosis has been detected in RA synoviocytes,^{127,128} the extent of synoviocyte apoptosis is not adequate to counteract ongoing proliferation. This imbalance is explained by a number of factors. First, FasL is expressed at relatively low levels on synovial T cells,¹²⁹ and soluble Fas or FasL competitors may impede Fas-induced apoptosis. Cytokines such as TNF, IL-1 β , and TGF- β 1, which are overexpressed in the joints of patients with RA, favor synoviocyte proliferation and inhibit susceptibility to apoptosis.¹³⁰⁻¹³² These and other signals reduce apoptosis of synoviocytes through activation of NF κ B and increased expression of antiapoptotic proteins, including X-IAP and Akt.^{133,134} Growth of the pannus is compounded by inflammatory changes such as oxidation that result in upregulation and mutations of the growth suppressor protein p53,¹³⁵ as well as IL-23, which promotes or stabilizes IL-17-producing Th cells (Figure 27-7). IL-23 has been shown to promote cell survival.¹³⁶

Observations regarding apoptosis regulators in RA are significant because they provide an opportunity for therapeutic manipulation. Local administration of anti-Fas monoclonal antibodies to human T cell lymphotropic virus-1 *tax* transgenic mice, or Fas ligand to collagen arthritis mouse models of RA, led to an improvement in arthritis.^{137,138} Several strategies used to modulate NF κ B attenuate the growth of synovial cells. Administration of TRAIL also attenuated experimental arthritis, although this was not thought to be due to apoptosis,¹³⁹ and an antibody to TRAIL-R2 (DR5) induced apoptosis of RA synovial fibroblasts.¹⁴⁰ Accumulating evidence suggests that fibroblasts in scleroderma may also be more resistant to apoptosis, and that TGF- β may promote this phenotype.¹⁴¹

Tissue Injury in Organ-Specific Autoimmunity

In contrast to systemic autoimmune diseases characterized by B lymphocyte stimulation, leading to antibody- and immune complex-mediated tissue injury, many organ-specific autoimmune diseases are caused by a cell-mediated attack, leading to the death of specific cell types within the organ. Cell targets are β cells of the islets of Langerhans of the pancreas in insulin-dependent diabetes mellitus, oligodendrocytes in the brain in multiple sclerosis, salivary and lacrimal glands in Sjögren's syndrome, and myocytes in polymyositis.¹⁴² Programmed pathways of cell death (apoptosis) can be implicated in the pathogenesis of some of these diseases, as is illustrated by the resistance of Fas-deficient (*lpr*) mice to diseases such as diabetes and experimental encephalomyelitis. In many of these diseases, cell death at the site of injury can be directly demonstrated by DNA fragmentation (TUNEL staining) in situ. Apoptosis is usually considered noninflammatory, but, as has been discussed, the context of cell death influences the immune response. For example, cytotoxic lymphocytes (CTLs) that induce cell death predominantly by perforin-mediated cell lysis (necrosis, although apoptotic changes are also observed through caspase 3 activation) or macrophage defects leading to delayed clearance of dying cells will promote the release of proinflammatory cytokines such as TNF. Similarly, death by pyroptosis or necroptosis releases inflammatory cytokines.

In most organ-specific autoimmune diseases, especially those for which adoptive transfers have been performed in animal models, CD4⁺ T cells have been shown to be critically involved in disease pathogenesis. Disease-promoting CD4⁺ T cells are restricted by major histocompatibility complex class II molecules, and therefore are unlikely to exert direct cytotoxic action on the class I-bearing target cell (although CD4⁺ T cells can upregulate FasL). CD4⁺ T cells may arm other effectors through the production of

Figure 27-7 Antiapoptotic phenotype of rheumatoid synovial fibroblasts. Cytokines and growth factors produced by macrophages and T cells lead to activation of nuclear factor kappa B (NF κ B) and overexpression of antiapoptotic proteins such as B cell lymphoma-2 (Bcl-2). Inflammatory stimuli, release of nitric oxide (NO), and reactive oxygen intermediates (O*) upregulate and induce mutations of p53. Infiltrating lymphocytes have a Fas ligand "low" phenotype.

cytokines (IFN- γ); they may induce tissue injury through a “bystander pathway” involving macrophages, or may induce receptors for cell death on the target cell “assisted suicide pathway.” In Sjögren’s syndrome in humans, controversy continues regarding whether Fas or FasL is constitutively expressed in normal salivary glands, but co-expression of these molecules in patients with Sjögren’s syndrome presumably causes cell death of acinar and ductal cells.¹⁴³

Inflammatory myopathies, such as polymyositis (PM) and dermatomyositis (DM), are autoimmune diseases that result in destruction of skeletal muscle fibers. Although Fas is upregulated on myocytes in these diseases, expression is also increased in nonautoimmune muscle disorders such as metabolic myopathies, denervating disorders, and muscular dystrophies, but not in normal human muscle tissue.¹⁴⁴ Detection of FasL on mononuclear cells invading the muscles in PM and DM patients with apoptosis of muscle cells implicates Fas/FasL in tissue injury in myositis.¹⁴⁵ Increased expression of the T cell cytotoxic mediator perforin in some PM and DM patients¹⁴⁶ indicates that granzyme-mediated myocyte injury is also involved. The tRNA synthetase antigens or their cleavage products may perpetuate inflammation by exerting chemotactic recruitment of immune cells through chemokine receptors.¹⁴⁷

Accelerated Apoptosis in Degenerative Rheumatic Disorders

Apoptosis of chondrocytes occurs during normal development of joints, and accelerated cell death may be important in diseases such as osteoarthritis (OA). The main mechanism underlying primary or secondary osteoarthritis is degradation of cartilage. Degradation is mediated by enzymatic and nitric oxide (NO)-induced breakdown of the extracellular matrix and insufficient new matrix synthesis. Normal and OA-derived chondrocytes in the superficial and middle cartilage zones—the major areas involved in early cartilage degeneration—express Fas and are sensitive to Fas-mediated death.¹⁴⁸ Chondrocytes obtained from patients with OA have enhanced spontaneous apoptosis in these zones compared with normal controls.^{149,150} Although NO is also capable of inducing apoptosis in chondrocytes, it does not seem to act through the Fas pathway.¹⁴⁸ In an experimental model of OA, transgenic mice lacking type II collagen, the main constituent of the extracellular matrix in cartilage, had high levels of apoptosis in their chondrocytes.¹⁵¹ Together, these findings suggest that apoptosis of chondrocytes plays a role in OA, and that inhibitors of NO synthesis may be of value in treating this disease (see reference 152 for review). The therapeutic use of intra-articular Fas agonists in RA may be deleterious to chondrocytes, whereas ADAM15 exerted a protective effect on chondrocyte apoptosis.¹⁵³

Osteoporosis is a common disorder resulting from increased bone resorption, decreased bone synthesis, or a combination of the two. Several reports support the concept that estrogen exerts its beneficial effect in preventing osteoporosis through induction of apoptosis in bone-resorbing osteoclasts,^{154,155} and glucocorticoid-induced osteoporosis may be explained by an increased rate of apoptosis of osteoblasts and osteocytes.¹⁵⁶ In the presence of macrophage colony-stimulating factor (M-CSF), osteoclasts differentiate

from a myeloid precursor common to macrophages and dendritic cells. In addition to numerous factors influencing bone turnover,¹⁵⁷ a soluble member of the TNFR family, osteoprotegerin (OPG) or osteoclastogenesis-inhibitory factor (OCIF), inhibits osteoclast activity after binding to its cognate receptor activator of NF κ B (RANK) ligand (OPG ligand/TRANSE).^{158,159} RANK ligand is expressed on osteoblasts and on activated T cells. Engagement of the membrane form of the receptor induces activation of NF κ B, thereby enhancing the formation, survival, and resorptive activity of osteoclasts.

Drugs That Affect Apoptotic Pathways

Up until very recently, therapy for inflammatory rheumatic disorders has been largely empiric. The types of drugs used include anti-inflammatory agents such as corticosteroids and nonsteroidals (NSAIDs), immunomodulatory drugs such as cyclosporine, and cytotoxic drugs such as cyclophosphamide and azathioprine. Because most of these drugs impinge on critical biochemical events within the cell, it is not surprising that they have effects on pathways of apoptosis.

Anti-inflammatory Drugs

Glucocorticoids at high doses induce the death of lymphoid cells through transcriptional regulation by the glucocorticoid receptor. Corticosteroids modulate expression of a large number of molecules that affect apoptotic programs—cytokines, cell cycle control proteins, c-myc, Bcl-2—and inhibit NF κ B activation, but the precise pathways that may operate in a cell-specific fashion¹⁶⁰ and that are relevant to clinical efficacy remain to be defined. Patients on long-term steroid therapy are susceptible to osteoporosis and osteonecrosis, which may be explained by bone loss caused by apoptosis of osteoblasts and osteocytes.¹⁵⁶

The major mechanism of action of NSAIDs consists of inhibition of cyclooxygenases (COXs), which reduce the production of proinflammatory cytokines and prostaglandins (see Chapter 59). NSAIDs also are effective in the chemoprevention of colorectal tumors in genetically susceptible individuals. Their antineoplastic properties may be explained by an increase in the prostaglandin precursor arachidonic acid, and by conversion of sphingomyelin to ceramide, a proapoptotic lipid.^{161,162}

Immunomodulatory Drugs

Cyclosporine and the closely related macrolide antibiotics, FK506 (tacrolimus) and rapamycin (sirolimus), have potent immunosuppressive properties and are used to prevent allograft rejection. These drugs modulate T and B cell immune responses by interfering with nuclear factor of activated T cell (NFAT)-mediated IL-2 gene transcription, NO synthase activation, cell degranulation, and apoptosis.¹⁶³ The reduced cytotoxic T lymphocyte activity is explained in part by impaired FasL induction secondary to the effect on NFAT,^{164,165} but effects on mitochondrial function have also been demonstrated. Certain cell types such as renal proximal tubules and synoviocytes or endothelial cells in RA may be more susceptible to the proapoptotic effects

of cyclosporine.¹⁶⁶ Rapamycin appears to be an effective and well-tolerated treatment for ALPS patients with glucocorticoid-resistant disease.¹⁶⁷

Cytotoxic Drugs

Many cytotoxic or immunosuppressive drugs that induce the suicide of lymphocytes, mostly through the p53 pathway (see Figure 27-4), exert some anti-inflammatory effect. Although methotrexate has effects on adenosine receptors, even low-dose methotrexate induces apoptosis of activated lymphocytes in vitro and in RA patients, probably in a Fas-independent manner.¹⁶⁸ Cyclophosphamide is an alkylating agent commonly used to treat many human cancers and severe autoimmune disease. Its efficacy has been attributed in part to apoptosis of tumor cells and perhaps of mesangial cells in glomerulonephritis.¹⁶⁹ Induction of apoptosis may also account for certain adverse effects, such as oligospermia or azoospermia and pancreatic β -cell destruction.

Bisphosphonates are the most potent antiresorptive drugs available and are widely used to treat various metabolic bone diseases, such as Paget's disease, bone tumor, ectopic calcification, and osteoporosis. Although individual members of this family differ somewhat in their effects, their general mechanisms of action include direct and indirect effects on osteoclast recruitment, function, and survival.¹⁷⁰

Biologics

The remarkable success of anti-TNF therapy for the treatment of RA, other arthritides, and Crohn's disease is generally attributed to blockade of TNF stimulation of the proinflammatory NF κ B pathway (see Figure 27-4).¹⁷¹ However, in Crohn's disease, it has been reported that anti-TNF monoclonal antibodies ameliorate disease by binding to cell-associated TNF and inducing apoptosis of macrophages and T cells.^{172,173} Both etanercept and infliximab induce apoptosis of monocytes/macrophages in RA synovial

tissue.¹⁷⁴ A monoclonal antibody that blocks RANK ligand (denosumab) has been approved for the treatment of osteoporosis.

B cell depletion therapy with antibodies against B cell surface proteins such as CD20 (rituximab) and CD22 (epratuzumab) are being used increasingly for therapy. The mechanisms of action of anti-CD20 have been studied most intensively in chronic lymphocytic leukemia (CLL) B cells. Rituximab depletes B cells by induction of apoptosis associated with downmodulation of Bcl-2 and X-IAP, by activation of complement, and by antibody-dependent cell-mediated cytotoxicity (ADCC).¹⁷⁵ Belimumab, a human monoclonal antibody that attenuates the activity of BLYS on B cell survival, has met its phase III objectives in clinical trials in SLE patients (see also Chapters 63 and 64).

OTHER OPPORTUNITIES FOR THERAPEUTIC INTERVENTION

Understanding the biochemical pathways that regulate apoptosis offers new opportunities for therapeutic intervention, many examples of which are given in the preceding section (Figure 27-8). In antibody-mediated diseases, induction of apoptosis of B cells is effective. In cell-mediated diseases such as Sjögren's syndrome and polymyositis, it may be beneficial to induce apoptosis of the cytotoxic effector cell. In diseases characterized by macrophage activation and inflammatory tissue growth, induction of macrophage apoptosis by anti-TNF reagents has already been shown to be effective in RA and in Crohn's disease (see Figure 27-8).

If a death receptor is selectively expressed on the cell to be killed, a death ligand could be administered. Examples of such a strategy include the use of Fas agonists or anti-TRAIL receptor antibodies in arthritis. Proapoptotic pathways could also be initiated from within the cell by peptide mimetics of Smac/Diablo (see Supplemental Figure 27-2 on www.expertconsult.com)¹⁷⁶ or through gene therapy approaches. Examples include blockade of NF κ B and

Figure 27-8 Avenues for therapeutic manipulation of apoptosis: biologics in practice or clinical trials. Anti-tumor necrosis factor (TNF) reagents work, in part, by engaging membrane TNF (mTNF) on activated macrophages and inducing apoptosis. Anti-CD20 antibodies eliminate B cells, in part by inducing apoptosis. Anti-BAFF/BLYS reagents reduce B cell and, possibly, macrophage survival. Antibodies to receptor activator of NF κ B ligand (RANKL) reduce differentiation or survival of osteoclasts. Estrogens promote osteoclast apoptosis, and bisphosphonates prevent it. Other approaches to modulation of apoptotic pathways are discussed in the text.

overexpression of Bax. Similarly, as was discussed earlier, a cytokine or an unwanted growth/differentiation promoter such as TNF in RA or OPG/RANK ligand in osteoporosis can be blocked by a monoclonal antibody or a soluble receptor fusion protein (see Figure 27-8).

In diseases in which apoptotic cell death leads to loss of organ function, the death ligand could be blocked by a monoclonal antibody or a soluble receptor fusion protein. Even when the death pathway has not been fully determined, attempts can be made to interfere with upstream components of apoptosis well before the “point of no return.” Antiapoptotic genes with limited (e.g., the protein FLIP blocks the Fas pathway) or broad (e.g., Bcl-2 family) specificity can be introduced into the cell. Further downstream, cell-permeable caspase inhibitors can block the execution phase of apoptosis in vivo, as has been illustrated experimentally.¹⁷⁷ All of these approaches are feasible, but they are limited by their potential adverse effects. Therapy must be relatively specific for the target cell, because widespread prevention of cell death for sustained periods is likely to predispose to neoplasia.

Because apoptotic cells themselves induce immunosuppression, infusion of apoptotic cells or natural antibodies that bind to apoptotic cells (see Figure 27-5) has been shown to attenuate experimental arthritis.^{178,179}

CONCLUSIONS

Appreciation that death and survival of cells are highly regulated and dissection of the biochemical pathways activated by different modes of intracellular stress have made an enormous contribution to our understanding of the pathophysiology of human disease. Inherited mutations of apoptosis regulatory molecules and of the genes encoding sensors may cause systemic autoimmunity, dysregulation, or misdirection of other cell death, or survival molecules contribute to a whole range of musculoskeletal disorders. Many of the drugs used to treat musculoskeletal disorders exert potent effects on apoptotic programs. New biologic therapies that induce or prevent apoptosis of selected targets are already in use in rheumatic diseases, and it is likely that many more, perhaps with greater selectivity, will be developed. All of these findings suggest that improved understanding of the regulation of apoptosis will continue to have great impact for the pathogenesis and therapeutic manipulation of rheumatic disorders.

Experimental Models for Rheumatoid Arthritis

RIKARD HOLMDAHL

KEY POINTS

Animal models are tools to mimic various aspects of rheumatoid arthritis (RA).

There are many different animal models for RA, including collagen-induced arthritis (CIA), collagen antibody-induced arthritis (CAIA), and adjuvant (pristane)-induced arthritis (PIA).

Arthritis can be induced in animals by immunization with cartilage components, nonspecific immune stimuli, bacterial or viral components, or genetic modification.

Animal models have a defined onset and are useful for the kinetic evaluation of arthritis, cell and mediator involvement, and detailed analysis of joint erosion.

Animal models provide direction for novel approaches to treatment such as cytokine inhibition.

For a deeper understanding of the complexity of the pathogenesis of rheumatoid arthritis (RA), the use of animal models is a necessity. Obviously a disease identical to RA cannot develop in experimental animals because they are different species with different genetics and environments, as compared with humans.

The advantages of using animal models are mainly the following:

1. Genetically controlling inbred animal strains.
2. Controlling their environment better than for humans.
3. Manipulating experiments. Researchers can change the genome of inbred strains by mutations, insertions, and deletions. They can also change the environment in a controlled way, such as immunizing or infecting animals, which may lead to arthritis. Controlled experiments can be performed.
4. Using animals is more ethical than using humans.

For animal models to be useful, they need to recapitulate some of the key features of RA, such as:

- The disease starts before the clinical diagnosis. An autoimmune and inflammatory process precedes the clinical onset by several years.
- Tissue specificity. RA is characterized by a tissue-specific inflammatory attack affecting diarthrodial, peripheral, and cartilaginous joints. Although systemic immune responses and manifestations are usually present, the inflammation is mainly directed toward peripheral joints.
- Chronicity. The disease is chronic and occurs in tissues in which no causative infectious pathogens have so far been demonstrated. Acute joint affections

are common manifestations in both physiologic responses to infections and in connection with other inflammatory disorders, but in RA chronicity is an essential characteristic. The disease course may proceed with identifiable relapses, but there is usually a steady progression of joint destruction.

- Autoantibodies. The development of RA is preceded and associated with elevated levels of autoantibodies in serum. Antibodies to citrullinated protein (ACPA) have the highest specificity and sensitivity followed by antibodies to immunoglobulin (rheumatoid factors), but antibodies to other antigens also occur in subsets of patients such as antibodies to type II collagen (CII) and hnRNP-A2.
- Major histocompatibility complex (MHC) class II association. The genetic influence is significant but complex. Class II genes in the major histocompatibility complex make the largest genetic contribution by far. In particular, certain structures in the peptide-binding pocket of HLA-DR4 molecules are highly associated with RA. Several other loci confirm that involvement of adaptive immunity (*PTPN22*, *CTLA4*, *IL-21*) strengthens the view that RA is an autoimmune disease.

Taken together, these findings suggest that both activation of innate immunity and immune-mediated inflammation directed to peripheral joints play a role in the disease process. Because the disease process starts several years before clinical onset with enhanced levels of autoantibodies (ACPA and rheumatoid factor [RF]) together with a higher level of inflammation markers, it is likely that the etiologic factors are operating at this early time. Smoking and various chronic infections such as periodontitis have been suggested to be associated with the early disease process. This process is, however, not joint specific and a further spreading of the autoimmune reactivities toward joint specificities is likely to occur before onset of arthritis. One possible explanation for such a response is an occurrence of an infectious agent persisting in the joint such an agent has not been identified as an explanation for RA, although infectious agents have been shown to induce and promote arthritis. Alternatively, the immune reaction could be directed to molecular targets in the joints, in cartilage, or in the synovial tissue. Another explanation could relate to a defect in a gene related to peripheral joints (e.g., leading to cartilage fragility or a gene affecting immune recognition). However, such a genetic defect has not been found. Instead, genome-wide association studies suggest that the MHC class II region contains the most important genes supplemented with a large number of genes outside the MHC region, most of which are associated with adaptive immune responses. Thus the cause and

driving forces are polygenic and multifactorial, and the understanding of the disease will require a detailed basic analysis of disease mechanisms. Animal models are excellent tools for this type of analysis. Recent advancement of different animal models mimicking different aspects of human diseases, as well as the improvement in genetic techniques, has dramatically increased their usefulness. The present overview includes not only models for RA but also briefly adds models with related disease pathways such as psoriasis arthritis, reactive arthritis, ankylosing spondylitis, Lyme disease, and septic arthritis (Table 28-1). However, there is a focus on the classical models for RA that are currently commonly used in both industry and academia: the adjuvant arthritis models in the rat, the collagen-induced arthritis (CIA), and the collagen antibody-induced arthritis (CAIA).

ARTHRITIS CAUSED BY INFECTIOUS AGENTS

Several infectious agents can invade joints, persist there, and cause arthritis. As with most persisting infectious agents, a balance between the parasite and the host is usually achieved. Thus inflammatory consequences may not only be caused directly by the parasite but also by an aberrant inflammatory response of the host. When microorganisms are present in the target tissue, chronic autoimmunity could be maintained by different mechanisms such as superantigen-mediated T cell activation, a cross-reactive immune response, or the presence of adjuvant material enhancing autoantigen presentation. Several such arthritogenic agents have been described in experimental animals, and some of these mimic a corresponding infectious disease in humans.

Mycoplasma arthritis Arthritis

Arthritis associated with mycoplasma infection is endemic among farm animals. It is also possible to induce arthritis in rodents after inoculation with *Mycoplasma arthritis*. However, mycoplasma bacteria are not easily found in RA joints, although they may cause arthritis in individuals with severe B cell deficiency.¹ Inoculation of mice induces a mild chronic arthritis in conjunction with the persistence of the microorganism.² In accordance with the observations in humans, B cell depleted mice are more susceptible to mycoplasma-induced arthritis.³

Lyme Arthritis

Borrelia is a spirochete that may persist in joints and cause arthritis. The clinical picture is chronic and resembles RA, and it is genetically associated with MHC class II-DR4, as is RA. Clearly, live bacteria persist in the joints but in many patients it has been difficult to identify the spirochete in the arthritic joints. Mice infected with *Borrelia* develop arthritis similar to the human disease.⁴ As in humans, MHC controls the susceptibility to arthritis and the immune response associated with human MHC class II expressed in mice has been shown to be directed to *Borrelia*-derived antigens.⁵ The persistence of the spirochete seems to be a requirement for the development of the arthritis,⁶ although

some mouse strains do not develop arthritis in spite of high levels of bacteria in the joints.

Staphylococcal Arthritis

Septic arthritis is most commonly caused by a persistent infection of *Staphylococcus aureus*. The bacteria tend to be encapsulated in tissues including joint synovia and persist for years. Inoculation with certain *S. aureus* strains induces septic arthritis in many mouse and rat strains.^{7,8} Severe and prolonged arthritis develops in infected joints mimicking the human situation. Interestingly, protection of the host is critically dependent on the innate defense such as neutrophils and complement, whereas the adapted immune response is not effective.⁹ Instead, the apparently aberrant adapted immune response promotes arthritis.^{10,11}

Arthritis and Ankylosing Spondylitis Induced by Intracellular Bacteria

Some bacteria with the capacity to invade cells on infection (e.g., *Yersinia*) are known to be related to postinfectious arthritides such as reactive arthritis and ankylosing spondylitis. These diseases are genetically associated with HLA-B27, a MHC class I allele of the B locus. It has been possible to reproduce the human disease to a large extent in HLA-B27 transgenic mice and rats.¹² In B27-transgenic rats, ankylosing spondylitis, balanitis, colitis, dermatitis, and arthritis occur spontaneously. However, if the rats are made germ free, the joint manifestations are no longer present, indicating the importance of a so far unknown infectious agent.¹³ A similar phenomenon has been shown to occur in B27 transgenic mice,¹⁴ in which arthritis occurs only in conventional animal facilities.

Arthritis Caused by Bacterial Fragments

Postinfectious arthritis can develop after bacterial infections. The occurrence of arthritis can be dependent on several different bacteria-derived compounds such as cell wall fragments, DNA, and heat shock proteins. Bacterial cell wall fragments are difficult to degrade and may cause prolonged activation of macrophages and synovial macrophages. The first animal model for RA to be described was the so-called *adjuvant arthritis* (mycobacteria cell wall-induced arthritis, MCWIA) induced in rats after injection of mycobacterium cell walls suspended in mineral oil (i.e., complete Freund's adjuvant [CFA]).¹⁵ Only rats (and not mice or primates) develop arthritis after mycobacterium challenge,¹⁶ although it has been reported that joint-related granuloma formation has occurred in humans treated with mycobacterium-containing vaccine.¹⁷ CFA is a potent adjuvant that activates a multitude of pattern recognition receptors, activating antigen-presenting cells enhancing T cell immunity. Subcutaneous injection of CFA in rats leads to granulomatous inflammation in many organs (e.g., the spleen, liver, bone marrow, skin, and eyes) and causes profound inflammation in peripheral joints.¹⁸ MCWIA is severe but self-limited, and the inflammation subsides after 5 to 7 weeks. The mycobacterium cell wall fragments are most likely disseminated throughout the body and engulfed by tissue macrophages, which have difficulties in

Table 28-1 Overview of Animal Arthritis Models

Model	Species	Genetics	Disease Characteristics	Reference
Arthritis Caused by Infection				
<i>Mycoplasma</i> -induced arthritis	Rats and mice	More pronounced in B cell-deficient mice	Mild chronic arthritis	2, 3
<i>Borrelia</i> -induced arthritis	Mice	MHC	Severe and erosive arthritis with spirochetes in the joints	4, 5
<i>Staphylococcus</i> -induced arthritis	Rats and mice	MHC	Severe arthritis	7, 8
Arthritis Caused by Bacterial Fragments				
<i>Mycobacterium</i> -induced arthritis (MCWIA)	Rats	MHC, non-MHC genes (LEW > F344)	Acute and generalized inflammatory disease including erosive arthritis	15
Streptococcal cell wall-induced arthritis (SCWIA)	Mice and rats	Non-MHC genes (LEW > F344), (DBA/1 = Balb/c > B10)	Severe and erosive arthritis	30, 31
Arthritis Induced by Adjuvant Stimulation				
Mineral oil-induced arthritis (OIA)	DA rats	non-MHC loci on chromosomes 4, 10	Acute and self-limited inflammation of peripheral joints	33, 48
Pristane-induced arthritis (PIA)	Rats	MHC, non-MHC loci on chromosomes 1, 4, 6, 12, 14	Chronic and erosive arthritis in peripheral joints	35, 47, 50
Pristane-induced arthritis (PIA)	Mice	MHC (q, d)? Balb/c, DBA and C3H gene backgrounds	Chronic and generalized inflammatory disease also affecting joints	53, 140
Unmethylated DNA-induced arthritis	Mice	DBA/1	Mild arthritis after intra-articular injection of unmethylated DNA or CpG oligonucleotides	26
Arthritis Induced by Cartilage Protein Immunization				
CII (heterologous or homologous CII in mineral oil)-induced arthritis (CIA)	Rats	MHC (a, l, f, and u), non-MHC loci on chromosomes 1, 4, 7, 10	Chronic and erosive arthritis in peripheral joints.	64, 80, 150
CII (heterologous or homologous CII in CFA)-induced arthritis (CIA)	Mice	MHC (q and r), non-MHC loci on chromosomes 1, 2, 3, 6, 7, 8, 10, 15	Erosive arthritis in peripheral joints	65, 77, 79, 81-84
CXI (rat CXI in IFA)-induced arthritis	Rats	MHC (f, u)	Severe, chronic, arthritis	102
Human proteoglycan (in CFA)-induced arthritis	BALB/c mice	MHC (d), several non-MHC loci	Chronic arthritis	60, 106
COMP (in mineral oil)-induced arthritis	Rats	MHC (u)	Acute arthritis	63
Passively Induced Arthritis Models				
Collagen antibody-induced arthritis (CAIA)	Mice, rats	Balb/c, DBA/1, C57Bl6	Acute self-limited arthritis	74
K/BxN serum-induced arthritis (SIA)	Mice	Balb/c, C57Bl6	Acute self-limited arthritis	131
Fibroblast transferred SCID mouse	Mice	Local injection of fibroblasts into immunodeficient SCID mouse	Sustained destructive arthritis	137
"Spontaneous" Arthritis Models				
HLA-B27 transgenic animals	Mice and rats	B27 heavy chain transgene	Ankylosing spondylitis, colitis, balanitis, arthritis	12, 14
The MRL/lpr mouse (mutation in the <i>fas</i> gene controlling apoptosis)	Mice	<i>lpr</i>	Generalized inflammation as a part of lupus disease, which also affects joints	119
Stress-induced arthritis	DBA/1 mice	Non-MHC genes	Enthesopathic response with no evidence for immune involvement. A model for psoriasis arthritis.	115
TNF transgenic mice (overproduction of TNF)	Mice	TNF transgene	Erosive arthritis, as well as generalized tissue inflammation	120
IL-1Ra-deficient mouse	Balb/c mice	IL1Ra deficiency	Arthritis	126
Gp130 IL-6R mutated mouse	C57 Black mice	IL-6R mutation	Arthritis	128
K/BxN arthritis	Mice	TCR transgenic on NOD	Severe arthritis due to transgenic encoded glucose 6 phosphoisomerase specific T cells	109
ZAP70 mutation	Balb/c mice	Spontaneous mutation in ZAP70 in Balb/c mice	Severe arthritis with autoreactivity	55
HTLV transgenic mouse	Mice	HTLV transgene	Erosive arthritis	136
HTLV transgenic rat	Rats	HTLV transgene	Generalized tissue inflammation	135

degrading the bacterial cell wall structures and are therefore transformed into an activated state, which trigger inflammation.

MCWIA can be abrogated by elimination of the classical α/β type of T cells and spleen-derived T cells^{19,20} can transfer the disease. The specificity of such T cells has, however, not been reproducibly demonstrated, although some possibilities have been suggested including bacterial structures and cross-reactive self-components.^{21,22} Although a role for heat shock proteins as T cell antigens has not been confirmed, they play a regulatory role for the development of arthritis.²³ In the search for the minimal arthritogenic structure in mycobacterium, it was observed that one of the essential structural elements of the mycobacterium peptidoglycan, muramyl dipeptide, could induce arthritis.²⁴ Interestingly, T cells do not recognize this structure, but it has potent adjuvant capacity as it activates the inflammasome by stimulating innate immune receptors (NOD2) and antigen-presenting cells.²⁵ The unmethylated DNA of bacteria has also been shown to independently trigger arthritis in mice²⁶ and contribute to arthritis severity of MCWIA in rats.²⁷ The bacterial DNA triggers Toll-like receptors on both antigen-presenting cells and inflammatory macrophages and will therefore interact with both T cell-dependent and inflammatory pathways. Another T cell-dependent arthritogenic pathway is triggered by the mineral oil in which the mycobacteria is suspended, as is discussed later in more detail.^{19,24} Thus this classical “adjuvant-induced arthritis” (MCWIA) is mediated by different and interacting pathways, dependent on both different mycobacterium cell components such as peptidoglycans, DNA, and heat shock proteins but also dependent on adjuvant activity mediated by the oil used to suspend the mycobacteria.

Postinfectious arthritis has also been observed to occur following streptococcal infections. A rapidly developing form of arthritis has been observed after systemic

inoculation of streptococcal cell wall fragments in rats²⁸ and mice²⁹ but not in primates.¹⁶ Peptidoglycans from the cell wall rapidly disseminate throughout the rat including the joints.³⁰ These structures are difficult to degrade for the macrophages, and as a consequence synovial macrophages are persistently activated. T cells are necessary for the initiation and perpetuation of the arthritis.³¹ Although the precise mechanisms are not known, it is possible that there are mechanisms shared with MCWIA.

Nonbacterial Adjuvant-Induced Arthritides

Research has found that the induction of arthritis in rats was dependent on not only the mycobacteria but also the oil into which the mycobacterium fragments were suspended. Interestingly, some oils supported the induction of arthritis, whereas others did not.³² Many years later it was noted that the mineral oils that supported the induction of arthritis were in fact arthritogenic by themselves.³³ It was also found that subcutaneous administration of nonbacterial adjuvant compounds such as pristane, hexadecane, and squalen were highly effective in inducing arthritis.³⁴⁻³⁶ These adjuvant compounds in most cases produce inflammation confined to the joints and offer more appropriate experimental models for RA than the earlier commonly used “adjuvant arthritis.”

Mineral oil-induced arthritis (OIA),³³ avridine-induced arthritis (AvIA),³⁴ pristane-induced arthritis (PIA),³⁵ hexadecane-induced arthritis,³⁷ and squalen-induced arthritis³⁶ in the rat share many common features but differ by the degree of chronic development³⁸ (Figure 28-1). They are induced with adjuvant compounds lacking immunogenic capacity (i.e., no specific immune responses are elicited). Instead they are rapidly spread throughout the body after a single subcutaneous injection, penetrate through cell membranes into cells, and interact with yet unknown cell surface receptors and intracellular proteins. One or two

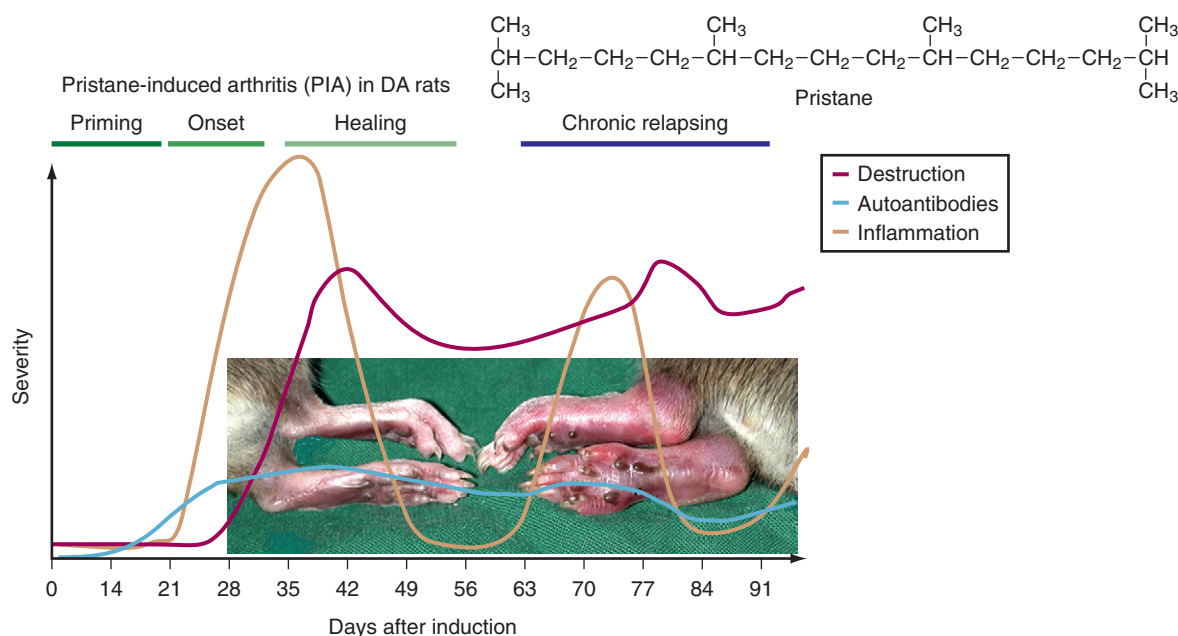

Figure 28-1 Pristane-induced arthritis in dark agouti rats. Induced with pristane subcutaneously. Development of severe and chronic relapsing arthritis starting 10 to 14 days after injection.

weeks after injection, arthritis suddenly develops. The arthritis appears in the peripheral joints, with a similar distribution as seen in RA. Occasionally other joints are involved, but systemic manifestations in other tissues have so far not been reported.³⁹ In certain rat strains, especially in the PIA model, the arthritis proceeds as a chronic relapsing disease. Interestingly, a systemic immune response leading to production of antibodies to RA33 and rheumatoid factors occurs, whereas no consistent immune response to specific cartilage components or citrullinated proteins has yet been observed.^{40,41}

A role for cartilage proteins in regulating disease activity is, however, still possible because the disease can be prevented and in fact therapeutically ameliorated by nasal vaccination with various cartilage proteins.⁴² Both the initiation and the chronic progression of the arthritis is T cell dependent as shown by in vivo administration of antibodies to α/β T cells.^{35,36,43} Together with the observation that the chronic disease course is associated with the MHC region,^{35,36,43} this could implicate an activation of T cells recognizing joint-derived proteins. However, T cell transfer of the disease seems to be oligoclonal rather than monoclonal and has so far failed to identify antigen-specific T cells.^{38,44,45} A role for environmental infectious agents is not likely because no difference in disease susceptibility could be seen in germ-free rats, although only conventional rats respond to heat shock proteins.⁴⁶ To date there is no evidence for recognition by lymphocyte receptors or receptors involved in the innate immune system. Surprisingly, some of the arthritogenic adjuvants are in fact components already present in the body before injection. For example, pristane is a component of chlorophyll and is normally ingested by all mammals including laboratory rats. Pristane is taken up through the intestine and spread throughout the body. However, they all share the capacity to penetrate into cells where they could change membrane fluidity and modulate transcriptional regulation and in higher doses induce apoptosis. The injection route and dose are critical (i.e., they determine which cell is first activated and to what extent).

The PIA model has been subjected to genetic analysis showing that the disease is polygenically controlled by at least 20 quantitative trait loci (QTL).^{47,48} These QTLs are often shared between the various forms of adjuvant arthritis and to a lesser degree also with CIA.⁴⁹ Interestingly, they seem to control distinct phases of the disease such as arthritis onset, clinical severity, joint erosion, and chronicity.⁴⁷ An approach to understand the complexity of the adjuvant arthritis, as well as the arthritis process in general, will be to eventually elucidate the underlying genetic polymorphism of these QTLs. This is, however, labor intensive and only a few genes and gene clusters have been positioned. The strongest effect is mediated through a polymorphism of the *Ncf1* gene spread in both inbred strains and wild rat populations. The *Ncf1* gene codes for the *p47phox* gene and controls the oxidative burst.⁵⁰ Surprisingly, a higher oxidative burst capacity was associated with more severe arthritis. The effect was found to operate before T cell activation and therefore also controls the degree of autoimmunity, linking innate and adaptive immunity. Importantly, the MHC region, which controls the adaptive T cell response,³⁵ and a C-type lectin gene cluster (APLEC),⁵¹ which is likely

important in uptake of antigen to antigen-presenting cells, have also been identified to control PIA.

Adjuvant arthritis is not easily inducible in species other than rats. Of the previously mentioned adjuvant-induced arthritis models, only PIA has been described in the mouse.^{52,53} However, the induction of PIA in mouse requires repeated intraperitoneal injections of pristane, which triggers a widespread inflammatory disease with a late and insidious onset. In fact, the induced disease mimics systemic lupus erythematosus (SLE) rather than RA.⁵⁴ The disease is clearly different from PIA in the rat; the same inducing protocol does not induce disease in the rat, and the disease course and characteristics are different. Another adjuvant-related model is the induction of mild arthritis after intra-articular injection of agents activating macrophages such as unmethylated DNA.²⁶ However, it has more recently been found that several mouse models earlier believed to be spontaneous are critically dependent on adjuvants and should therefore be classified as adjuvant-induced arthritis. From the observation that a BALB/c substrain in Japan spontaneously developed arthritis, a mutation in the ZAP70 was identified.⁵⁵ The ZAP70 mutation (W163C) caused weaker TCR-mediated signaling, and the development of arthritis was preceded by increased levels of IL-17-producing autoreactive T cells. The ZAP70 mutation led to defective positive selection and the emergence of autoreactive T cells attacking the joints. As a result, both rheumatoid factors and CII reactive antibodies were detected in the mice. However, the arthritis did not develop in specific pathogen free-housing conditions and it could be shown that injection of β -glycan or mannan induced the arthritis.^{56,57} Thus this model seems to be an adjuvant-induced arthritis in the mouse.

Other spontaneous arthritis models, the KxB/N model and the IL-1R deficient mouse, have been shown to be mediated by a likely adjuvant component because arthritis did not develop or was dramatically attenuated under germ-free conditions.^{58,59} The causative arthritogenic effect could be shown to be mediated by intestinal bacteria, segmented filamentous bacteria (SFB), and lactobacillus, respectively.

Taken together, there is today a set of useful adjuvant-type arthritis models in both mice and rats.

Cartilage Protein-Induced Arthritis

Arthritis is inducible with several different cartilage proteins such as aggrecan,⁶⁰ link protein,⁶¹ type XI collagen CXI,⁶² cartilage oligomeric matrix protein (COMP),⁶³ and CII. These various models have different characteristics and genetics. CIA, induced with CII, is today the most commonly used model for RA. It was first demonstrated in the rat⁶⁴ and was later reported using other species such as mouse⁶⁵ and primates.⁶⁶ Today CIA is the most commonly used model for RA.

Collagen (II)-Induced Arthritis

Immunization with the major collagen in cartilage, type II collagen (CII), leads to an autoimmune response and as a consequence, sudden onset of severe arthritis. Although it is usually necessary to emulsify the CII in adjuvant such as mineral oil in the rat and complete Freund's adjuvant in the

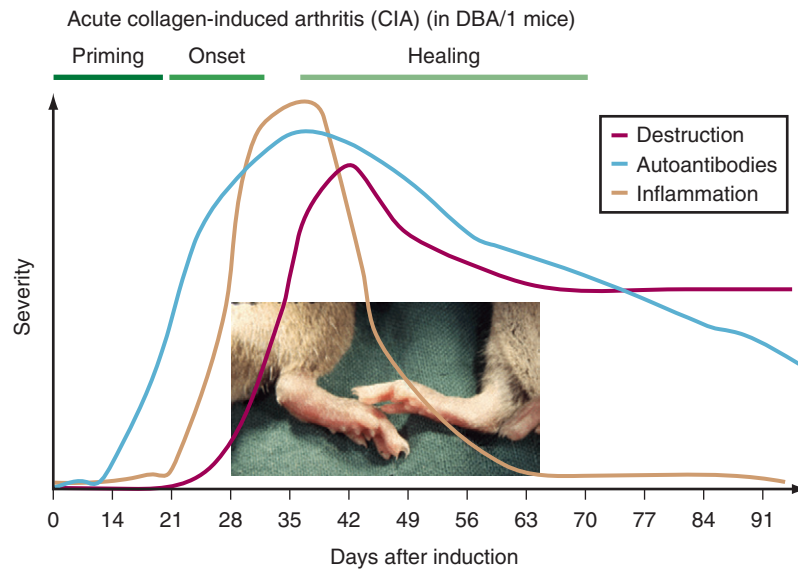

Figure 28-2 Collagen-induced arthritis in DBA/1 mice. Induced after immunization with heterologous (bovine, chicken, rat) type II collagen emulsified in complete Freund's adjuvant. Severe arthritis starts 3 to 4 weeks after immunization. Although the arthritis is severe and gives dramatic erosions and bone remodeling, there is no chronic relapsing inflammatory disease course.

mouse, the disease can be distinguished from the various forms of adjuvant arthritis.⁶⁷ However, the CIA model varies considerably depending on the experimental animal strain, the adjuvant used, and whether CII used is of self or nonself origin.

In both rats and mice immunized with heterologous CII, a severe, erosive polyarthritis develops 2 to 3 weeks after immunization but usually subsides within 3 to 4 weeks (Figure 28-2). The most commonly used DBA/1 strain thus develops a severe but only an acute disease. However, a genetic influence is obvious because mice on C57Bl/10 backgrounds develop a milder arthritis that later may develop into a more chronic relapsing disease course⁶⁸⁻⁷⁰ (Figure 28-3). In all of the models the erosive inflammatory phase is followed by a healing phase with pronounced

formation of new cartilage and bone that clinically can be difficult to distinguish from active inflammation. The disease is critically dependent on both T cell and B cell responses to CII, and pathogenic antibodies play a role in the inflammatory attack on the joints.^{71,72} The CAIA is inducible with certain CII-specific monoclonal antibodies⁷³ (Figure 28-4). These CII-specific antibodies bind to the cartilage and destabilize the cartilage matrix. Subsequently the inflammatory response is triggered with infiltration of antibodies into cartilage matrix, fixation of complement attraction of neutrophilic granulocytes, and activation of FcR expressing inflammatory cells in a process independent of the immune system.^{74,75} Interestingly, the epitopes recognized on CII contain arginines that potentially can be citrullinated. Recently it could be shown that one of the

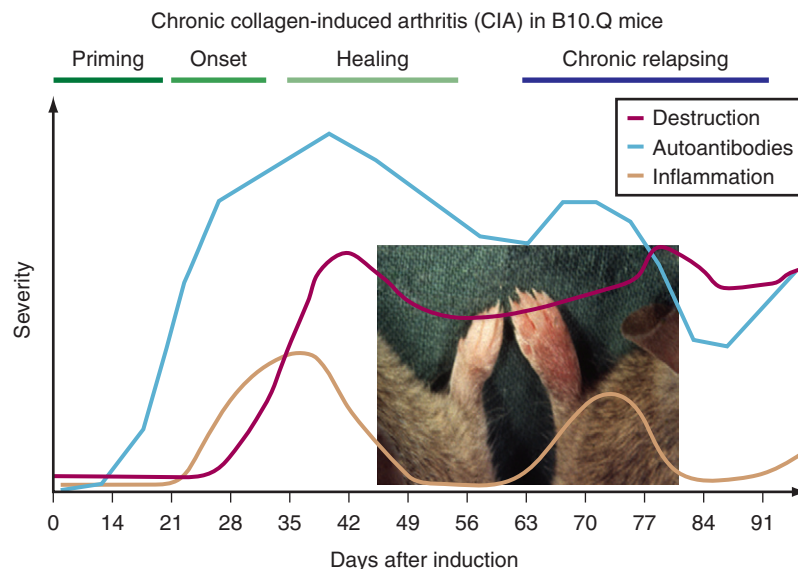

Figure 28-3 Collagen-induced arthritis in B10.Q mice. Induced after immunization with rat type II collagen emulsified in complete Freund's adjuvant. Mild arthritis starts 3 to 5 weeks after immunization. The arthritis is mild but gives inflammatory joint erosions and bone remodeling. It is, however, often followed by a chronic disease with inflammatory relapses.

Figure 28-4 Collagen antibody-induced arthritis (CAIA) in Balb/c mice. Induced after intravenous injection of a defined set of monoclonal antibodies to type II collagen. Mild arthritis starts 48 hours after injection, and severe arthritis starts after an additional boost with injection of LPS intraperitoneally. The arthritis is acute with mild joint erosions but with no bone remodeling. The disease is acute and resolves within a few weeks.

major CII epitopes is citrullinated, and monoclonal antibodies specific for the citrullinated peptide induce arthritis showing an important link to RA.⁷⁶

The disease induced after immunization with homologous CII in both rats and mice is not as easily inducible, but once started it is severe and tends to be more chronic than the disease induced with heterologous CII.⁷⁷ The pathogenic events in the chronic disease phase are largely unknown but are most likely dependent on both autoreactive B cell and T cell activity. Nevertheless, the CIA model is the most extensively investigated model for RA and has given valuable insights into the genetic control of the arthritic process and of the autoimmune interactions with cartilage. It has also been useful for the development of new therapeutic approaches and for drug screening.

Genetic Basis of Collagen-Induced Arthritis

Susceptibility to CIA varies dramatically between different inbred strains. The CIA is a complex, polygenic disease, similar to the adjuvant arthritis models described earlier. In the CIA model the autoimmune process is already determined by the induction through immunization with a defined antigen. Not surprisingly, the MHC class II polymorphism is important for determining susceptibility,^{78,79} but there is also a major influence by a large number of genes outside the MHC region. The major gene regions have been identified through genetic segregation experiments in both mice and rats, which have given an overall picture of the genetic inheritance of the susceptibility.⁸⁰⁻⁸² As in other complex diseases, these genes operate in concert and can only be identified through isolation in a controlled genetic and environmental context.^{83,84} So far MHC class II genes (*Aq*), *Ncf1*, and complement C5 have been positioned from genetic analysis. The *Ncf1* gene was defined through analysis of PIA and CIA in rats.⁵⁰ A spontaneous mutation in the mouse *Ncf1* gene, when combined with the CIA-susceptible MHC class II allele *Aq* in the C57Bl/10 mouse, develops a

chronic relapsing form of CIA.⁷⁰ In addition, these mice tend to develop a severe form of chronic arthritis in the postpartum period, with the spontaneous development of autoimmunity to CII.⁷⁰ Another genetic polymorphism of importance is the complement C5, which is deficient in many mouse strains. The deficiency leads to a relative resistance to CIA, suggesting a role for complement pathways in arthritis,⁸⁵ which in fact is opposite of its role in mycoplasma-induced arthritis.⁸⁶ A role for alternative complement pathways and Fc receptor-mediated pathways has been demonstrated using both CIA and the CAIA models.⁸⁷⁻⁹¹ The rapid progress of genome-wide association analysis of large human cohorts today gives direct information on involved genes and gene clusters in common diseases such as RA. However, the animal models are necessary to understand their functional relevance; for this, the genes controlling the corresponding disease in the animals need to be identified.⁹² Knowledge of animal model genetics will facilitate creation of humanized models through genetic modification.

Role of the Major Histocompatibility Complex

Early observations using the CIA model in both mice and rats indicated a role for the MHC region. In the mouse, CIA induced with either heterologous or homologous CII is most strongly associated with the H2^q and H2^r haplotypes, whereas most other haplotypes such as b, s, d, and p are relatively resistant.⁷⁹ The major underlying gene within the H2^q haplotype has been identified as *A^q beta*.⁷⁸ Moreover, the immunodominant peptide derived from the CII molecule bound to the arthritis-associated q variant of the A (*A^q*) molecule has been found to be located between positions 259 and 271 of CII.^{93,94} This peptide can be glycosylated on the central lysine side chain and is recognized by most of the CII-reactive T cells.⁹⁵ Interestingly, the peptide is also bound by DR4 (DRB1*0401/DRA) and DR1 molecules (i.e., the shared epitope), which are associated with

RA. Mice transgenically expressing DR4 or DR1 are susceptible to CIA and respond to CII259-271 peptide,^{96,97} and CII-reactive T cells from RA patients seem to predominantly recognize the glycosylated forms of the CII259-271 peptide.⁹⁸ These findings suggest a model for studies of RA that not only mimic some basic pathogenic events but may also share some critical structural similarities.

Arthritis is also inducible in mouse strains that do not express q or r. A commonly used model is to induce arthritis with high doses of chicken or bovine CII emulsified in *Mycobacterium tuberculosis*-containing CFA.⁹⁹ T cell autoreactivity to CII has not yet been reproducibly demonstrated, however, and it is possible that the T cell reactivity is directed to a contaminant in the preparation such as another matrix protein or the pepsin used for the preparation. Such T cell reactivity could help B cells produce antibodies to CII, explaining the development of arthritis.

Autoimmunity in Collagen-Induced Arthritis

It is important to emphasize that the identified structural interaction between MHC class II–positive peptide complexes and T cells does not give us the answer to the pathogenesis of CIA (or RA), but rather a better tool for further analysis. An important question is how the immune system interacts with the peripheral joints (i.e., how autoreactive T and B cells are normally tolerized and what happens in the pathologic situation, after their activation by CII immunization). Most of the T cells reactive with the rat CII259-271 peptide do not cross-react with the corresponding peptide from mouse CII. The difference between the heterologous and the homologous peptide is position 266 in which the rat has a glutamic acid (E) and the mouse an aspartic acid (D), which leads to a weaker binding of the mouse peptide to A^q. The importance of this minor difference was demonstrated in transgenic mice expressing CII mutated to express a glutamic acid at this position.¹⁰⁰ When mutated CII was expressed in cartilage, the T cell response to CII was partially but not completely tolerized. The mice were susceptible to arthritis, but the incidence was low, similar to what is seen in mice immunized with homologous CII. This finding shows that a normal interaction between cartilage and T cells leads to the activation of T cells, but with less capacity to induce arthritis or with regulatory properties. These CII autoreactive T cells may under extreme circumstances (such as CII immunization) be pathogenic. In contrast, B cells reactive with CII are not tolerized and as soon as the T cells are activated, even in a partially tolerized state, they may help B cells to produce autoreactive and pathogenic antibodies. It is possible that a similar situation in humans could explain the difficulties in isolating CII-reactive T cells compared with the relative ease in which CII-reactive B cells can be detected in the joints.

Induction of Arthritis with Other Cartilage and Joint-Related Proteins

Type XI Collagen-Induced Arthritis

The type XI collagen (CXI) is structurally similar to CII and is to a large extent co-localized. CXI is a heterotrimer with three different α chains, one of which is shared with CII

(the $\alpha 3$ chain). Both heterologous and homologous CXI have been reported to induce arthritis in rat strains.^{101,102} Interestingly, the induction with homologous CXI gives a chronic relapsing disease, which is distinctly different from the heterologous CXI-induced disease and CII-induced CIA.

COMP-Induced Arthritis

Another cartilage protein is cartilage oligomeric matrix protein (COMP). Homologous COMP induces arthritis in both rats and mice.^{63,103} In comparison with CIA, the resulting disease is self-limited, is less erosive, and has a different genetic control.

Proteoglycan (Aggrecan)-Induced Arthritis

Other major components of joint cartilage are proteoglycans, of which the largest is aggrecan. Immunization of Balb/c mice with fetal human aggrecan induces chronic arthritis.⁶⁰ Both B and T cells are involved in the pathogenesis. Autoreactive T cells have been isolated and respond to the G1-domain of aggrecan in which neoepitopes are created¹⁰⁴ and T cell receptor transgenic mice spontaneously develop arthritis at high age.¹⁰⁵ The disease has been genetically mapped and shown to share many gene regions in common with CIA.¹⁰⁶

Antigen-Induced Arthritis

Antigen-induced arthritis is a classical model of RA that is induced by immunizing animals with a foreign antigen, usually bovine serum albumin, and subsequently injecting the same antigen into a joint. As a result, a pronounced T cell–dependent, immune complex–mediated, and destructive arthritis develops in the injected joint. The model is well controlled and has been used to understand the effector phase of the cartilage destruction.¹⁰⁷

Glucose-6-Phosphoisomerase-Induced Arthritis

The successful induction of arthritis after immunization with recombinant glucose-6-phosphoisomerase (G6PI) in adjuvant¹⁰⁸ stems from the identification of the K/BxN model in which transgenic T cells specific for GPI lead to spontaneous arthritis in NOD mice.¹⁰⁹ The GPI-induced arthritis is MHC dependent and associated with the H2q haplotype (as CIA),¹¹⁰ and it has been shown that GPI peptides with an A^q binding capacity can induce arthritis.¹¹¹ Interestingly, GPI has a unique affinity for cartilage as it binds with high affinity to cartilage proteoglycans¹¹² and spontaneous immune activation in the K/BxN mouse seems to primarily arise in lymph nodes draining joints.¹¹³ Thus although GPI is ubiquitously expressed, the immune system may recognize its presence in the joints.

Spontaneous Arthritis

Many of the classical inbred mouse and rat strains tend to spontaneously develop arthritis,¹¹⁴⁻¹¹⁶ in particular under certain environmental influence (Table 28-2). In some strains such as DBA/1, the grouping of males easily induces

Table 28-2 Some Environmental Effects on Mouse Arthritis

Environmental Effect	Effect on Arthritis	Reference
Intermale stress	+	115
Pregnancy	—	151
Postpartum	+	70, 144
Estrogen	—	143
Darkness	+	152
Infections (segmented filamentous bacteria)	+	58

+, increased arthritis; —, decreased arthritis.

intermale aggressiveness and such stress seems to be associated with development of severe arthritis.¹¹⁵ This stress-induced arthritis is different from inflammatory arthritis models like CIA and has less inflammatory synovial infiltrate, but enthesopathy and new cartilage and bone formation, more similar to psoriasis arthritis than RA,^{117,118} dominate the joint pathology.

In addition, a number of genetic mutations strongly enhance arthritis development. One such mutation has been shown to occur in the *Fas* gene, of critical importance for apoptosis. In the MRL mouse background, arthritis develops together with a severe lupus disease.¹¹⁹ More recent research found that a mutation in the T cell receptor-signaling molecule Zap70 was associated with severe arthritis in Balb/c mice housed under conventional but not specific pathogen-free conditions.⁵⁵

Spontaneous Arthritis in Genetically Modified Strains

Importantly, models developing spontaneous arthritis have been possible to create by genetically modifying mouse strains. The prime example of this is the demonstration that overexpression of tumor necrosis factor (TNF) leads to severe arthritis.¹²⁰ This model has been extremely useful in delineating the role of TNF in mediating arthritis. Other genetic mutations leading to overexpression of TNF also lead to spontaneous development of severe arthritis such as deletion of an upstream regulatory element controlling TNF secretion in fibroblast¹²¹ or the deletion of DNaseII¹²² leading to aberrant secretion of TNF by chronically stimulated macrophages. Mice overproducing TNF develop arthritis irrespective of a functional immune system, which is thus operating entirely through innate inflammatory mechanisms.^{123,124} Another important lesson from the TNF-overproducing mice was that it primarily led to the development of arthritis, although in some situations colitis and encephalomyelitis could also develop.^{121,125}

Subsequently several other genetically modified mouse strains developing arthritis have been reported. A mouse deficient for the IL-1 receptor antagonist¹²⁶ developed arthritis that not only affected the downstream effector functions but could also be shown to be dependent on T cell activation.¹²⁷

A mutation in the gp130 IL-6 receptor was observed to lead to arthritis in elderly mice.¹²⁸ Interestingly, the mutation led to an accumulation of polyclonal autoreactive CD4⁺ T cells secreting inflammatory cytokines, indicating a regulatory role of the IL-6 receptor of the adaptive immune system.¹²⁹

Another type of spontaneous arthritis was observed in a T cell receptor transgenic mouse in which the TCR recognizes a peptide derived from the ubiquitously occurring protein G6PI bound to the MHC class II protein Ag7.^{109,130,131} Importantly, however, the arthritis does not develop if the mice lack the SFB bacteria in the intestinal flora, indicating that this disease is not strictly spontaneous but rather induced by a bacterial adjuvant stimulation.⁵⁸ Research indicates that the pathogenic effector pathway in this model depends on antibodies reactive with G6PI.^{130,131} The arthritis can be transferred with such antibodies and bind to the cartilage surface, mimicking the pathogenesis of anti-CII antibodies in the CAIA model. The use of the G6PI antibody-induced arthritis has been instrumental in finding early inflammatory steps in the joint attack, which involves complement activation through the alternative pathway, mast cell activation, and neutrophil infiltration.¹³²⁻¹³⁴ Clearly the joints are specifically targeted in the disease, and it remains to be determined how T cells and antibodies recognize this systemically expressed autoantigen in a joint-specific context.

A transgenic model in which spontaneous arthritis has been observed is in mice and rats transgenic for the envelope protein of human T cell leukemia virus 1.^{135,136} In this case there is not only joint inflammation and autoimmunity to CII but also widespread inflammatory infiltrates in skin, salivary glands, and vessels.

Another type of model is the induction of arthritis after transplantation of human synovial fibroblasts into immune-deficient SCID mice.^{137,138} The same type of arthritis develops after transfer of murine fibroblast cell lines.¹³⁹ This model is likely to reflect inherent properties of fibroblast-mediated mechanisms showing different features as compared with other arthritis models like CIA and PIA.¹³⁹

These models most likely represent various aspects of the processes leading to arthritis, which will be determined by the transgene or defective gene or due to transplantation of specific cells.

USING ANIMAL MODELS

Increasing Knowledge of Disease Pathways

An ideal model for human RA should mimic the complexity of the human disease in being polygenic and dependent on environmental factors. The animal models have the advantage that both genetics and environment can be better controlled. RA is a syndrome, likely composed of several distinct disease entities as are the animal models.

Ideally, the animal models should mimic the various subtypes of RA and with increasing knowledge of RA such as the identification of ACPA as a predictive biomarker and the identification of new genes associated with RA, there will also be new demands on the animal models. Thus there is not yet an animal model reflecting the production of ACPA,¹⁴⁰ nor have proper humanized mice been developed that pathophysiologically mimic the genetic polymorphism identified in humans. For introducing new genes (e.g., human MHC class II) or environmental factors (e.g., smoking), a proper and well-controlled genetic and

environmental context is critical. For example, the introduction of the human MHC class II as transgenes in the mouse has led to a number of artifacts, some of them related to the nonphysiologic interactions between human and mouse genes. However, as long as the mouse models have been studied with a well-controlled genetic and environmental context, they have and will contribute with detailed information on the molecular pathogenesis leading to arthritis. For this work, the possibility to genetically modify both mice and rats is a powerful tool and the possibility to make controlled experiments is a critical advantage.

Developing New Therapeutic Strategies

To test new drugs and therapies it will be necessary to select from the different models available. Obviously there is no optimal model for RA, and there will never be one. The models described, however, are useful because they represent different aspects of RA pathogenesis. Thus depending on the questions to be asked or symptoms to be treated, different models may be used. The most common model today used for testing new therapeutic approaches is the CIA model, which should be included as a reference model. The usefulness of this model has been confirmed with the anti-TNF treatment, which was subsequently introduced in RA.¹⁴¹

Recapitulating the three hallmarks for RA discussed earlier—tissue specificity, chronicity, and MHC association—reasonable criteria should be that the animal models should display these hallmarks. A common mistake is to only use acute models and to only use disease prevention and not established chronic disease as a readout. It is also of critical importance to be aware of the specific environmental influences on arthritis development in rodents (Table 28-3). Of particular importance are stress effects, which are easily produced by mixing mice from different litters in the same cage and which will lead to cage-dependent effects.¹¹⁵ Other important factors are sex hormones¹⁴²⁻¹⁴⁴ and most likely also neurohormones,^{145,146} which play an important role in modulating disease activity—seen as effects by estrous cycling, pregnancy, and light effects. Clearly, environmental and genetic effects need to be controlled. The control of genetics is usually achieved by testing standardized inbred strains. The problem is that these vary considerably between different colonies mainly due to genetic contamination. In spite of these problems, there is no question that both environment and genetics can be better controlled in experimental animal models than can be achieved in studies directly involving the human population.

Table 28-3 Some Environmental Effects on Rat Arthritis

Environmental Effect	Effect on Arthritis	Reference
Noise stress	++	153
Predator stress	—	154
Estrogen	—	155
Testosterone	—	155
Infections	—/+	13, 46, 156, 157

+, increased arthritis; —, decreased arthritis.

Ethical Considerations. One important drawback of using experimental models for RA is suffering of animals. However, in the light of various human activities that use animals, the use of them in research is readily defensible. In fact, it could be unethical not to use them for research because it would prohibit further understanding of human diseases, thereby letting humans suffer from something curable or preventable. It should also be emphasized that the recent development of animal models for RA has refined them to be of more specific use, which has decreased animal suffering. For example, the historically most commonly used model for RA, the *Mycobacterium*-induced adjuvant arthritis, is a systemic and severe inflammatory disease, whereas pristane-induced arthritis and collagen-induced arthritis are more specific diseases of the joints.

CONCLUSIONS

Experimental animal models are essential tools for not only investigating the basic mechanisms leading to RA but also developing new therapies. Many models have been described, and each represents different aspects of the disease. Therefore it is important to use different models. The models for RA described so far can be divided into four principal different groups: (1) adjuvant induced, (2) cartilage protein induced, (3) passively induced, and (4) spontaneous. Of emphasis is that the models used should reflect essential hallmarks of RA such as tissue specificity, chronicity, and MHC class II gene association, and they should reflect the fact that RA is a polygenic disease triggered by unknown and multifactorial environmental factors.

KEY POINTS

The sensory nervous system regulates peripheral inflammation, including release of mediators such as substance P and calcitonin gene-related peptide.

The sensory nervous system processes nociceptive stimuli through pain pathways, which can be amplified by inflammation.

During inflammation, an efferent systemic response increases activity of the hypothalamic-pituitary-adrenal axis and the sympathetic nervous system while decreasing activity of the hypothalamic-pituitary-gonadal axis and the parasympathetic nervous system.

Inflammation leads to partial loss of sympathetic nerve fibers in inflamed tissue and in secondary lymphoid organs, which enhances proinflammatory activities via $\alpha 1/2$ -adrenergic pathways.

Recruitment or activation of neurotransmitter/neuropeptide-producing cells in inflamed tissue is an anti-inflammatory signal.

For over 2000 years (since Celsus and Galen), clinicians recognized that cardinal features of neurogenic responses, such as redness, warmth, swelling, and pain, are rapid sequelae of inflammation. Neurogenic vasodilatation reported in 1876 by Stricker and in 1901 by Bayliss^{1,2}; the inflammatory axon reflex with erythema observed in the 1910s by Bruce and by Breslauer^{3,4}; the flare response reported by Lewis around 1930 with erythema, hyperalgesia, and edema⁵; rediscovery of the antidromic vasodilatory flare response and dorsal root reflex by Chapman⁶; and Kelly's and Jancsó's more extended concepts of neurogenic inflammation in the 1960s^{7,8} all were expressions of the same principle: the influence of sensory afferent nerve fibers on acute inflammation and on cardinal clinical signs of inflammation. In the past two decades, our view has expanded to include the sympathetic and parasympathetic efferent nervous systems in inflammatory/immune control.

The concept of neuronal regulation of inflammation is supported by reports of patients with hemiplegia and chronic inflammatory diseases, in whom the paralytic side is protected from inflammation (Table 29-1). Cases have been reported in which hemiplegia manifested long after the outbreak of chronic inflammatory disease or long before, leading to protection independent of the time point (see Table 29-1).

In addition, clinical observations demonstrate neuronal regulation of inflammation in that symptoms of many chronic inflammatory diseases have diurnal variation, with

Neural Regulation of Pain and Inflammation

RAINER H. STRAUB

greater activity in the night and early morning hours. Because the rhythm of circadian changes in clinical signs depends on superordinate control of the hypothalamic nucleus suprachiasmaticus, a functional connection is revealed between the central nervous system (CNS), efferent pathways of the CNS (hormonal and neuronal), and the inflammatory/immune response.⁹

Neuronal regulation of inflammation is dependent on a robust innervation of lymphoid organs and the direct influence of neurotransmitters/neuropeptides on immune cells. Although sympathetic nerve fibers usually follow arteries (also branching into vessel-free regions), sensory nerve fibers have their own routes along vessels or independent of the vasculature. In addition, nerve fibers of the parasympathetic nervous system innervate many tissues in the head, neck, and trunk of the body, and upper and lower limbs are excluded. The greatest support for a neuroimmune contact comes from innervation of lymphoid organs, where nerve fibers are responsible for neuronal regulation of immune responses.¹⁰⁻¹²

The receptors for neurotransmitters are present on almost all immunocompetent cells. Some exceptions are known, such as the absence of $\beta 2$ -adrenergic receptors on T helper type 2 cells.¹³ The differential and time-dependent expression of receptors can shape the neuroimmune cross-talk. Sometimes receptor expression is increased or decreased in the context of an inflammatory response.¹⁴⁻¹⁶ The time-dependent involvement of different immune cells and receptor expression in the course of a given disease is probably important for neuronal regulation of inflammation.

In addition, intracellular signaling pathways of neurotransmitter receptors are dependent on environmental conditions; this has been demonstrated for G protein-coupled receptors.^{17,18} Another control process of these receptors involves regulators of G protein signaling (RGS), and tumor necrosis factor (TNF) can lead to increased desensitization of G α protein-coupled receptors.¹⁹ For additional details on some receptors of neurotransmitters on immune cells, the reader is referred to the literature.^{13,20}

In the study of neuronal regulation of inflammation, the bipolar role of neurotransmitters is important. For example, norepinephrine binds to α - and β -adrenergic receptors, which exert opposing effects on intracellular signaling cascades ($\alpha 1$: increase in diacylglycerol and protein kinase C; $\alpha 2$: decrease in cyclic adenosine monophosphate [cAMP]; β : increase in cAMP). Although norepinephrine binds to α -adrenergic receptors at between 10^{-9} and 10^{-5} mol/L, it binds to β -adrenergic receptors only at concentrations equal to or higher than 10^{-7} mol/L (typical serum level: 10^{-9} mol/L; typical tissue concentration: 10^{-7} mol/L). Because α -adrenergic effects (proinflammatory) are markedly different from β -adrenergic effects (anti-inflammatory),

the concentration of norepinephrine in the environment of an immune cell is very important for noradrenergic effects. The situation is very similar for adenosine via A1 adenosine receptors (e.g., α -adrenergic) and A2a/b adenosine receptors (e.g., β -adrenergic). It is important to note that this behavior is typical for many neurotransmitters/neuropeptides because more than one receptor can be a binding partner, and different receptors have opposing intracellular signaling pathways.²¹ In conclusion, neuronal regulation of inflammation is an important aspect of the inflammatory process.

The role of neuronal reflexes can be explored by examining three key phases of the inflammatory process: (1) phase 1 includes first inflammatory actions within the first 12 hours; (2) phase 2 describes inflammation from several hours to several days until resolution of inflammation (the normal wound healing process); and (3) phase 3 starts with the onset of chronic inflammatory disease that does not properly resolve.

During evolution, mechanisms were positively selected that serve to overcome acute transient inflammatory episodes but not chronic lifelong inflammation, because of the negative selection pressure.^{22,23} Transient inflammatory episodes, for example, include infections, wound healing responses, foreign body reactions, immune reactions during pregnancy, and others.^{22,23} Mechanisms of these short-lasting episodes are also used in chronic inflammatory diseases. From this point of view, it is meaningful to start with an acute transient inflammatory episode such as a wound response after injection of foreign material into the skin.

ACUTE INFLAMMATION (THE FIRST 12 HOURS)

Recognition of Foreign or Pathogenic Material: Immune and Pain Pathways

After injection of foreign material into the skin, there are two categories of recognition: (1) recognition by local cells and (2) systemic recognition. These two forms of recognition are interwoven, and the strength of the local response accounts for the magnitude of systemic involvement (see later).

Systemic recognition of foreign material occurs in highly specialized nerve endings of sensory afferent, nociceptive nerve fibers (the nociceptor). Nerve endings of sensory afferent nerve fibers possess an impressive array of receptors

that are responsible for instant activation of the nerve fiber (Figure 29-1).^{24,25} Upon introduction of foreign material, infectious agents can pose a threat, which can elicit a neuronal response via pattern recognition receptors on polymodal nociceptors (e.g., the Toll-like receptors) (see Figure 29-1). In addition, factors such as bradykinin, prostaglandins, and cytokines from activated mast cells and other cells can stimulate their respective receptors on sensory nerve terminals (see Figure 29-1). Under consideration of these mechanisms, peripheral recognition of foreign material by nociceptors is part of the innate immune response. Moreover, mechanical irritation, noxious cold/heat, and low pH concentration stimulate the sensory afferent nerve fiber (see Figure 29-1). Altogether, this leads to an orthodromic action potential that stimulates the dorsal root ganglion (DRG) and releases elements such as substance P into the wounded peripheral tissue (efferent function of sensory afferents). The spreading reaction is attributed to the axon reflex and the dorsal root reflex, which lead to antidromic activation of neighboring sensory afferents, resulting in local expansion of the immediate flare response.^{24,26,27}

Substance P is one of the strongest chemotactic and vasodilatory factors; it leads to instant plasma extravasation and accumulation of neutrophils, monocytes, and other cells.²⁸⁻³⁰ Substance P and other neuropeptides increase vascular leakage and interstitial fluid volume in connective tissue capsules, tendons, and muscles, leading to stiffness. In addition, substance P immediately stimulates activities of mast cells, monocytes, macrophages, dendritic cells, and neutrophils to reflexively increase local proinflammatory responses. Parallel to substance P, calcitonin gene-related peptide (CGRP) with strong vasodilatory and chemotactic activities is released. The third sensory neurotransmitter is the excitatory amino acid glutamate, whose proinflammatory effects have been described.³¹ The fourth neurotransmitter of sensory afferent nerve fibers is galanin, which possibly has dual proinflammatory and anti-inflammatory roles, depending on receptor subtypes (but data are limited with respect to effects on immune cells).³²⁻³⁴ All these neurotransmitters/neuropeptides are locally secreted into the vicinity of the peripheral nerve terminal.

In addition to local effects of these neurotransmitters/neuropeptides, pain signals are transmitted to the brain and elicit a systemic response (Figure 29-2). The pathways ascend through sensory nerve fibers (A δ or C fibers), the

Figure 29-1 The mechanisms of a polymodal nociceptor. The figure schematically depicts receptors on and neuropeptides of nerve fiber endings of sensory afferent nerve fibers. The list of receptors is not complete. α AR, alpha adrenoceptors; AMPA, α -amino-3-hydroxyl-5-methyl-4-isoxazole-4-propionic acid; ASICs, acid-sensing ion channels; BR, bradykinin receptor; CGRP, calcitonin gene-related peptide; EAAR, excitatory amino acid receptor; GFRs, growth factor receptors; HRs, histamine receptors; IL, interleukin; IRs, inhibitory receptors; NK1, neurokinin 1; NMDA, *N*-methyl-D-aspartate; NPY, neuropeptide Y; PAR, protease-activated receptor; PR, prostaglandin receptor; SP, substance P; TLRs, Toll-like receptors; TNF, tumor necrosis factor; TRPA1, transient receptor potential ankyrin 1; TRPM8, transient receptor potential menthol 8; TRPV1, transient receptor potential cation channel V1.

neurons in the DRG, the neurons in the spinal medulla, and the contralateral spinothalamic tract to reach the medial and lateral thalamus, cortical areas S1 and S2, the hippocampus, and other brain regions responsible for affective components of pain (anterior cingulate cortex, insula, and prefrontal cortex)³⁵ (see Figure 29-2). All parts of the pain pathway can be sensitized under the influence of inflammatory stimuli. Sensitization means stabilization and amplification of nociceptive stimuli.

Peripheral Sensitization

Sensitization appears already during the earliest phase of inflammation, as demonstrated in the kaolin/carrageenan or similar instant chemical models. Nevertheless, sensitization is a dynamic process that changes over time, as demonstrated by inflammation-induced induction of transient receptor potential vanilloid-1 (TRPV1) receptors on DRG neurons, gradual infiltration of macrophages into the DRG, or bilateral long-term upregulation of bradykinin receptor B2 in the DRG and dorsal horn.³⁶⁻⁴⁰ Thus, sensitization plays a role throughout all inflammatory phases, but the underlying mechanisms might change over time.

In normal tissue, nociceptors have high thresholds. However, during inflammation, these thresholds are lowered and nociceptors are sensitized.^{25,41} Lowering of the nociceptor threshold is a consequence of converging stimulatory inputs into the nerve terminal via different receptor pathways (see Figure 29-1). These high-threshold units, defined as nociceptors by their high mechanical threshold, become sensitized and start to respond to light pressure and movements in the working range of the joint (Figure 29-3A).

Most of these units are thin myelinated fibers (A δ fibers) or unmyelinated fibers (C fibers). Furthermore, mechanoin-sensitive and thermoinsensitive “silent” nociceptors are sensitized in inflamed tissue, and they start to respond to mechanical and thermal stimuli during inflammation.^{25,41} This class of receptors is characterized by long-standing responses to algogenic factors, and they are important in neurogenic inflammation.^{25,42} These mechanisms are summarized under the heading of peripheral sensitization (the “S” in Figure 29-2).

It is important to note that injection of proinflammatory cytokines such as interleukin (IL)-6 and TNF into the joint leads to a huge increase in the number of action potentials recorded from afferent fibers supplying the joint. Both IL-6 and TNF have the potential to sensitize afferent nerve fibers in the joint to mechanical stimulation contributing to mechanical hypersensitivity.^{43,44} These effects can be blocked by anticytokine therapy with biologic agents,^{43,44} and it is expected that this also inhibits release of proinflammatory substance P and other neuropeptides.

Central Sensitization

In the DRG and spinal cord, peripheral inflammation makes neurons hyperexcitable and more susceptible to input from sensory nerve fibers (the “S” in Figure 29-2). This amplifies the response through additional activation of adjacent and even remote spinal neurons far away from the inflamed region, leading to expansion of the receptive field.^{25,41} The peripheral inflammatory response increases expression of substance P, CGRP, and bradykinin with their respective receptors in the DRG and dorsal horn.^{45,46} In the dorsal

Figure 29-2 Pain pathways in the human body. Upon activation of Aδ and C fibers in peripheral tissue, sensory afferents transmit signals to dorsal root ganglia and, finally, to the spinal medulla. The signal is transmitted to the thalamus and cortex via the spinothalamic tract. On all levels, sensitization of input can happen, leading to stabilization and amplification of the pathway ("S" in yellow circle). Interneurons transmit the signal to sympathetic efferents and motoneurons to induce immediate responses. This latter connection leads to compartmentalization of the response because only site-specific sympathetic nerve fibers and somatomotor nerve fibers are involved. S, sensitization; st. T., spinothalamic tract.

horn, substance P potentiates the release of factors such as glutamate and aspartate.⁴⁷ The ipsilateral response can lead to contralateral co-activation of the DRG and sensory afferents,³⁶ which might contribute to symmetric manifestations of inflammation.^{48,49} Bilateral upregulation of, for example, neurokinin 1 and bradykinin 2 receptors has been demonstrated, whereby this phenomenon was strictly segmental and not general.³⁶ Sometimes spinal sensitization persists beyond the peripheral nociceptive or inflammatory process, and the character of pain changes from an inflammatory to a neuropathic form.⁵⁰ In experimental arthritis, such a shift

from inflammatory to neuropathic features of sensitization has been demonstrated by increased expression of a typical marker of neuropathic pain, ATF3, and by the favorable effects of gabapentin treatment in a postinflammatory phase of hypersensitivity.⁵⁰

Spinal sensitization is often a consequence of increased release of excitatory amino acids (glutamate, aspartate, and glycine), substance P, CGRP, neurokinin A, and galanin from nociceptor neurons and upregulation of the respective receptors in the spinal medulla. Enhanced release can be induced by peripheral inflammation.^{24,25,41,51}

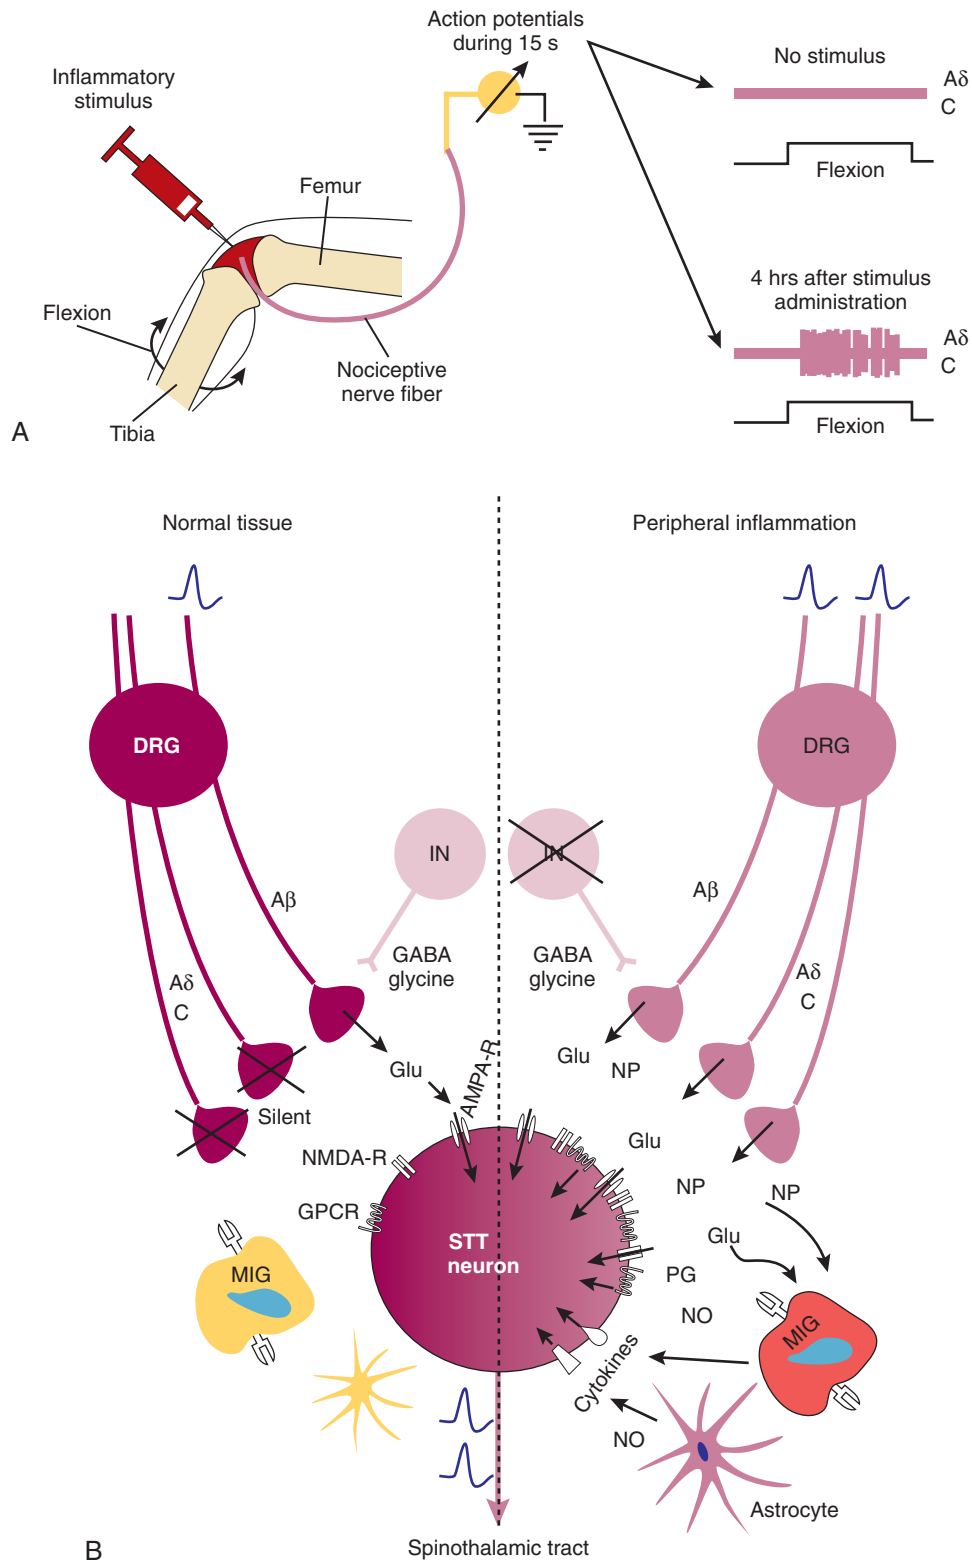

Figure 29-3 Mechanisms of peripheral and central sensitization. **A**, Peripheral sensitization. Injection of an inflammatory stimulus leads to an increase in the number of action potentials as recorded from afferent fibers supplying the joint.^{13,14} Peripheral sensitization is mediated by a plethora of heterogeneous receptors on afferent fibers (see Figure 29-1). **B**, Spinal central sensitization. *Left*, In the normal situation, only A β fibers are activated (upon mechanical stimuli); these are low-threshold nonnociceptive fibers that release glutamate (Glu). On the postsynaptic neuron, only α -amino-3-hydroxy-5-methyl-4-isoxazole-4-propionic acid (AMPA) receptors are activated and opened.^{13,14} *Right*, In the inflammatory situation, previously high-threshold A δ and C fibers are activated by pressure, leading to release of glutamate and neuropeptides (NPs) such as substance P and calcitonin gene-related peptide (CGRP). This leads to activation of the postsynaptic membrane via AMPA (AMPA-R) and *N*-methyl-D-aspartate (NMDA) receptors (NMDA-R), neuropeptide receptors, prostaglandin receptors, and cytokine receptors (particularly, IL-1 β , IL-6, TNF). These changes lead to long-standing hypersensitivity. DRG, dorsal root ganglion; GABA, γ -aminobutyric acid; GPCR, G protein-coupled receptor; IN, interneuron; MIG, microglia; NMDA, *N*-methyl-D-aspartate; NO, nitric oxide; NP, neuropeptide; PG, prostaglandin; STT, spinothalamic tract. The star-shaped cell is an astrocyte.

Non-*N*-methyl-D-aspartate (NMDA) receptors but also NMDA glutamate receptors are relevant in joint inflammation (Figure 29-3B).^{52,53} Sensitization can be mimicked experimentally by intrathecal administration of substance P or NMDA via an increase in prostaglandins or cyclooxygenase-2.⁵⁴ In addition to the activating pathway, there exist inhibitory pathways via, for example, γ -aminobutyric acid (GABA) or glycine.⁵⁵ Second, spinal sensitization is dependent on microglial cells and astrocytes, which can aggravate pathologic pain states in which cytokines and chemotactic factors play an important priming and perpetuating role (see Figure 29-3B).^{56,57} Cytokines such as IL-1 β , IL-6, and TNF play a dominant role in cytokine-induced hypersensitivity,^{56,57} and these cytokines are induced in the spinal cord during experimental arthritis.⁵⁸

Several proinflammatory intracellular signaling pathways have been implicated in priming of microglia and pain-processing neurons. It is not easy to distinguish whether signaling cascades in neurons, microglia, or other cells are important, because experimental studies using microdialysis or intrathecal administration of pathway inhibitors do not target a specific cell type. Nevertheless, these studies clearly demonstrate the importance of factors such as nuclear factor κ B (NF κ B),⁵⁹ protein kinase A,⁶⁰ protein kinase C,^{61,62} c-Jun N-terminal kinase,⁶³ JAK/STAT3 signaling pathway,⁶⁴ p38 mitogen-activated protein kinase (MAPK),⁶⁵⁻⁶⁷ Src-family kinase,⁶⁸ arachidonic acid pathways,⁶⁹ and others. These pathways typically lead to intraneuronal calcium and sodium accumulation, which is an excitatory signal.^{24,41}

For example, the p38 pathway was demonstrated to be an important proinflammatory signaling cascade in spinal neurons and microglial cells in experimental arthritis.⁶⁵ Phosphorylated p38 is increased in microglial and neuronal cells during the course of experimental arthritis. Intrathecal administration of a specific p38 inhibitor led to decreased synovial inflammation but also to suppressed articular cytokine and protease expression and joint destruction as measured by radiographic and histology scores.⁶⁵ This effect was dependent on the presence of TNF in the spinal cord. TNF can be a signaling element upstream of p38 by activating p38-phosphorylating kinases, or downstream of phosphorylated p38 that induces TNF secretion. It was demonstrated that intrathecal, but not subcutaneous, TNF neutralization with etanercept inhibited p38 phosphorylation and peripheral inflammation.⁶⁵ The positive effect of intrathecal spinal TNF neutralization was confirmed in another model of experimental arthritis.⁷⁰ In this model, peripheral joint inflammation was decreased, and pain-related behavior was drastically reduced.⁷⁰

It is interesting that all mentioned pathways belong to proinflammatory cascades initially described in peripheral immune cells. In contrast, anti-inflammatory pathways such as adenosine A1, β -adrenergic, and δ/μ -opioidergic receptor pathways are inhibitory in microglial activation paradigms.⁷¹⁻⁷⁵ For instance, spinal administration of an A1 adenosine receptor agonist markedly reduced inflammation, as well as bone and cartilage destruction, in an experimental arthritis model.^{71,72} Administration of the A1 adenosine receptor agonist also decreased nuclear c-Fos expression in the superficial and deep dorsal horns of the spinal medulla.

In addition, the A1 adenosine receptor agonist decreased the density of astrocytes in these areas.⁷² This indicates that, along with neurons and microglial cells, astrocytes are involved in sensitization.

Finally, understanding why peripheral and central sensitization was conserved during evolution is important. Sensitization of pain has a protective role because it warns about potential danger, enables us to remove noxious stimuli, and stimulates wound management. Furthermore, avoidance of painful situations in the future would be desirable. This is nicely indicated by the fact that peripheral inflammatory stimulation of sensory neurons can induce central IL-1 β release in the hippocampus,⁷⁶ a cytokine that is instrumental in hippocampal learning phenomena.⁷⁷ Sensitization is an amplification factor that should last as long as painful or noxious stimuli are present (or even a little longer to stimulate wound management). Thus, sensitization is a supportive factor of innate immunity. It has been positively selected as an evolutionarily conserved learning phenomenon that will not be stopped until inflammation is terminated (i.e., the stimulus is removed).

Neuroendocrine Systemic Response

Parallel to the local inflammatory reaction, hormonal and neuronal systemic responses are engaged. The hormonal response system is mainly the hypothalamic-pituitary-adrenal (HPA) axis, which is stimulated through activation of sensory pathways or through circulating cytokines.⁷⁸ Activation of the HPA axis can happen on adrenal, pituitary, and hypothalamic levels.⁷⁸ Neuronal efferent response systems include the sympathetic nervous system and the parasympathetic nervous system.

The systemic response of the HPA axis and the sympathetic nervous system is an “energy appeal reaction” that serves allocation of energy-rich fuels from stores to the highly catabolic immune system (Figure 29-4).^{79,80} This re-allocation of energy-rich fuels is important throughout the inflammatory response. The energy demand of the immune system can contribute to a systemic response whose long-standing use is detrimental to homeostasis (see Figure 29-4).^{79,80}

In the course of inflammation, the sympathetic nervous system is activated via direct spinal interneurons that link sensory inputs to sympathetic output (see Figure 29-2, blue lines). This has the advantage that the input defines the location of the output, which leads to confinement of the response to the affected area. In addition to the central coupling of sensory and sympathetic pathways, sympathetic nerve fibers communicate with sensory nerve terminals by way of α 2-adrenergic and prostaglandin cross-signaling at the level of the peripheral nerve terminal.^{81,82} This inflammation-induced cross-signaling leads to higher activity of sensory afferents. Systemically, the sympathetic nervous system, similar to the HPA axis, is activated through stimulation of sensory pathways or through circulating cytokines (e.g., IL-6). Activation of the sympathetic nervous system is the main factor in re-allocating energy to the immune system (see Figure 29-4).

Although systemically relevant inflammation is coupled to increased sympathetic nervous tone and increased activ-

Activation of the HPA axis and the sympathetic nervous system at the onset of inflammation prepares the immune system for most naturally occurring immune challenges.⁸⁵ Activation of the HPA axis mobilizes immune cells, leading to redistribution of neutrophils, monocytes, and natural killer (NK) cells.⁸⁵ The sympathetic nervous system can support the very acute inflammatory process in phase 1 because of six main mechanisms: (1) mobilization of immune cells from systemic stores (similar to the HPA axis),⁸⁵ (2)

support of plasma extravasation,⁸⁶ (3) remodeling of tissue by inducing matrix metalloproteinases,^{87,88} (4) stimulation of nociceptors via $\alpha 2$ -adrenergic and prostaglandin cross-signaling,^{81,82} (5) chemoattractant activity of sympathetic neurotransmitters,⁸⁹ and (6) liberation of free fatty acids and glucose necessary for the activated immune system (see Figure 29-4). In summary, during the first hours of inflammation, the HPA axis and the sympathetic nervous system are mainly proinflammatory.

Vagal afferents from the intestine and liver play an important role in modulating a systemic milieu that increases or decreases the magnitude of very acute inflammatory hyperalgesia, which depends on the agent, the stimulus strength, and epinephrine secretion from the adrenal medulla.^{90,91} The vagal tonus determines the overall reflex modulation of very acute inflammatory processes, and vagal afferents are important in perception of inflammatory conditions in the abdomen.^{92,93} Reports in the last decade have demonstrated that lipopolysaccharide-induced inflammation can be inhibited by electrical vagus stimulation of the distal end of the dissected vagus nerve.⁹⁴ These very acute vagal effects were dependent on the sympathetic innervation of the spleen.⁹⁵ In addition, carrageenan-induced leukocyte recruitment into a pre-formed subcutaneous air pouch was inhibited by vagus nerve stimulation of the intact vagus nerve.⁹⁶ This was done without dissection of the vagus nerve so that afferent and efferent vagus nerve effects cannot be separated.⁹⁶

Administration of an intrathecal p38 inhibitor (mentioned earlier), which has favorable effects in experimental arthritis, largely increases vagal activity.⁹⁷ Because spinal application of p38 inhibitors blocks aspects of central sensitization,⁶⁵ one would expect blockade of segmental sympathetic outflow, as demonstrated in Figure 29-2 (blue lines). A decrease in central pain signaling, and thus decreased hypothalamic activation of the HPA axis and sympathetic nervous system, and diminution of segmental sympathetic outflow most probably increase parasympathetic reflex activity. Particularly in very early inflammation, this should be a favorable anti-inflammatory feature. These acute vagus experiments were complemented by experiments in long-standing chronic inflammation models (see later).

INTERMEDIATE INFLAMMATION (BETWEEN 12 HOURS AND SEVERAL DAYS/FEW WEEKS)

Almost all experimental systems dissecting neuroinflammatory pathways have been performed under very acute inflammation conditions (within minutes to 12 hours, reflecting an experimental working day). Much less information is available after 12 hours until termination of uncomplicated inflammation with normal wound healing. Within the mentioned time span, many additional immune/inflammatory responses appear, such as increased local cell accumulation, antigen transport to secondary lymphoid organs, antigen processing, clonal expansion of lymphocytes, release of lymphocytes from secondary lymphoid organs, and access of antigen-specific cells to the target tissue.

In this phase of inflammation, mechanisms discussed in the very early phases can still apply. However, they might

change over time because tissue innervation is altered. Immune/inflammatory effector responses relevant in this phase are modulated by neurotransmitters, which can differ from very acute inflammation.

Local Cell Accumulation in Inflamed Tissue

Local cells accumulate in inflamed tissue as a consequence of cell mobilization and chemotaxis. The major neurotransmitters/neuropeptides of sensory afferents (substance P) and of sympathetic efferents (norepinephrine) are potent chemotactic factors for innate immune cells, such as neutrophils, monocytes, and eosinophils. The direct chemotactic effect of substance P has been demonstrated by injecting substance P into the skin; this leads to upregulation of the endothelial adhesion molecule E-selectin (CD62E) and, for example, attraction of eosinophils to the injection site.⁹⁸ Similarly for the sympathetic nervous system, the lack of catecholamine production in animals with a deletion of the dopamine- β -hydroxylase gene leads to a strong reduction of leukocyte accumulation in the adventitia and periaortitis of vessels.⁹⁹

Substance P and norepinephrine also have strong chemotactic effects in vitro.^{89,100} The sympathetic co-transmitter neuropeptide Y and the sensory co-transmitter CGRP also have chemotactic effects.^{89,101} The effects of substance P and norepinephrine can be amplified by increasing secretion of potent chemotactic factors such as IL-8.^{102,103} In addition, norepinephrine and substance P can upregulate matrix metalloproteinases to soften the tissue.^{87,88,104}

Immediate Change in Neuronal Innervation

Upon entry of monocytes and neutrophils into the tissue, these cells become activated and can engulf pathogens or foreign material. Activation of these cells is mediated by pattern recognition receptors, as well as by other proinflammatory mediators and inflammasome-derived products, leading to activation of neutrophils and differentiation of entering monocytes into macrophages or dendritic cells.¹⁰⁵

In striking contrast, norepinephrine and its potent co-transmitter adenosine (made from sympathetically released adenosine triphosphate [ATP]) inhibit many proinflammatory effects of activated innate immune cells such as monocytes, macrophages, NK cells, and neutrophils via β -adrenergic and A2 adenosine receptor signaling.¹⁰⁶ In this context, it is important to mention that ectonucleotidases (CD39 and CD73), which convert purine precursor neurotransmitters to adenosine, are increased in inflammation.¹⁰⁷⁻¹⁰⁹ A classic example of A2-adenosine-mediated or β -adrenergically induced inhibition of cells is the strong negative effect on neutrophil or monocyte/macrophage phagocytosis and on the function of dendritic cells. The important role of adenosine as an inducer of regulatory T lymphocytes has been carefully documented.¹¹⁰ Because innervation is balanced in tissue with similar densities of sensory and sympathetic nerve fibers, this dichotomy of substance P and norepinephrine/adenosine is counterproductive for innate immunity.

Activated macrophages and stimulated tissue fibroblasts start to produce nerve growth factor (NGF), which supports

the outgrowth of sensory and sympathetic nerve fibers equally well. In other words, NGF is not specific for sensory or sympathetic nerve fibers. Indeed, inflammatory tissue releases large amounts of NGF, as, for example, is substantiated in rheumatoid arthritis (RA) or experimental arthritis.^{111,112}

Activated macrophages and fibroblasts also produce nerve repellent factors such as semaphorin 3C and semaphorin 3F.^{113,114} These two factors specifically repel sympathetic nerve fibers and have no effect on sensory nerve fibers, which instead are repelled by semaphorin 3A.^{113,114} In addition, sensory nerve fibers sprout under the influence of NGF into inflamed tissue, leading to a preponderance of substance P over sympathetic neurotransmitters.¹¹⁵ Such a sensory hyperinnervation is also observed in skin wounds when sympathetic nerve fibers are absent.¹¹⁶ Loss of sympathetic nerve fibers is a rapid process that

is observed soon after initiation of experimental inflammation.¹¹⁷⁻¹¹⁹ It can also be observed in vitro with the use of repellent factors in neurite outgrowth assays (within a few hours).¹¹⁴

Repulsion of sympathetic nerve fibers and sprouting of sensory nerve fibers are important ways to initiate a proinflammatory environment in the later phase of inflammation. As shown in Figure 29-5, the appearance of two noradrenergic zones (β : normal/healthy; α : inflamed tissue) is a consequence of this process. It is important to mention that loss of sympathetic nerve fibers is observed not only in inflamed tissue but also in the spleen^{117,118,120} and in the lymph nodes. In the former, loss of sympathetic nerve fibers is evident in the white pulp (T cell proliferation area); similarly, these fibers are not observed in B cell follicles.^{117,121} In the same animals, sympathetic nerve fibers sprout into the hilus area of the spleen and do not reach the distal white pulp (T cell

Figure 29-5 Loss of sympathetic nerve fibers and sprouting of sensory nerve fibers into inflamed tissue. Loss of sympathetic nerve fibers leads to generation of two distinct noradrenergic zones. In a zone with low concentrations of neurotransmitters (the red α -adrenergic zone), only α -adrenergic effects are possible because of the affinity of noradrenaline for the two receptor subtypes (high for α , low for β). However, in the vicinity of sympathetic nerve terminals, α - and β -adrenergic effects can be expected (green β -adrenergic zone). Sympathetic nerve fibers on the healthy side of the demarcation line support β -adrenergic mechanisms such as release of free fatty acids (FFAs), whereas on the other side of the demarcation line, norepinephrine supports proinflammatory α -adrenergic signaling and pain induction via α_2 -adrenergic receptors on nerve terminals of nociceptive neurons. In parallel, sensory nerve fibers sprout into inflamed tissue, leading to dissociation of innervation between sympathetic and sensory nerve fibers. The proinflammatory milieu is stabilized. The dissociation is a consequence of specific nerve fiber repulsion of sympathetic but not sensory nerve fibers. In the symptomatic phase of the disease, neurotransmitter-producing cells appear whose anti-inflammatory capacities are too small to overcome inflammation. CNS, central nervous system; FFA, free fatty acid; TNF, tumor necrosis factor.

or follicles (B cell). Thus, a proinflammatory milieu is established in secondary lymphoid organs, as in peripherally inflamed tissue.

Role of Catecholamines in Antigen Transport to Secondary Lymphoid Organs and Immune Response

After antigen capture, a further important aspect of inflammation is the transport of processed antigenic material to secondary lymphoid organs. Transport to lymphoid organs is mediated by lymphatic vessels, whose pumping efficiency is decreased by β -adrenergic pathways and is stimulated by α -adrenergic signaling.^{122,123} In addition, migration of antigen-loaded dendritic cells is stimulated via α 1-adrenergic mechanisms.¹²⁴ It is important to note that immature dendritic cells migrate upon α 1-adrenergic influence, but CD40-stimulated mature dendritic cells do not (those that arrived in secondary lymphoid organs and encountered T cell contact via CD40–CD40 ligand).¹²⁴ Thus, rapid establishment of an α -adrenergic zone in peripheral tissue is probably important in inducing migration of dendritic cells. In addition, substance P supports dendritic cell maturation and activity.^{125,126}

Catecholamine and its co-transmitter adenosine influence the direction of the immune response, whether T helper type 1 or type 2. Detailed in vitro experiments show that norepinephrine via β -adrenergic pathways inhibits T helper type 1 cell priming by inhibiting IL-12 and stimulating IL-10 of dendritic cells.^{20,127} The effects of catecholamines on the T helper type 17 immune response are not known. Tolerogenic effects of adenosine have been described.¹¹⁰ In addition to reactions on T cells, norepinephrine inhibits antigen presentation by epidermal Langerhans cells; this event is β -adrenergically mediated.¹²⁸ Already in the late 1980s, it was demonstrated that surface expression of the antigen-presenting molecule human leukocyte antigen (HLA) class II was inhibited by β -adrenergic signaling.^{129,130}

In summary, the sympathetic nervous system has many inhibitory roles via β 2-adrenergic and A2-adenosine receptors when T helper type 1 cell priming participates (e.g., in arthritis). The opposite occurs in a situation with T helper type 2 conditions because norepinephrine stimulates IL-4 and IL-10; this occurs along with many stimulating effects on B cells and antibody production (e.g., in systemic lupus erythematosus).²⁰ Because norepinephrine and adenosine have additional strong inhibitory effects on secretion of TNF, interferon (IFN)- γ , and IL-2 via β -adrenergic and A2 adenosine pathways, the general inhibitory aspect of these neurotransmitters at high concentrations, along with vasoactive intestinal peptide (VIP) and CGRP, is well established.^{131,132}

At low concentrations of norepinephrine, when α 1/2-adrenergic signaling is dominant, even stimulating effects on TNF occur.^{133,134} Thus, β -adrenergic influence in peripheral tissue and in secondary lymphoid organs should be reduced during proinflammatory T helper type 1 cell priming. Similar sympathetic nerve fiber loss and establishment of distinct α - and β -adrenergic zones belong to an adaptive process in secondary lymphoid organs to support or inhibit immune responses toward distinct antigens.

Clonal Expansion of Aggressive and Regulatory T and B Cells

The antiproliferative effects on T cells of norepinephrine via β -adrenergic receptors have been documented by many investigators.^{20,135} The proliferative response of CD8⁺ T cells is inhibited to a greater extent than that of CD4⁺ T cells, presumably because CD8⁺ T cells have a greater number of β -adrenergic receptors, and this effect is mediated via inhibition of IL-2 secretion.¹³⁵ A proliferative effect of norepinephrine via β -adrenergic receptors is known for B cells.^{20,136,137} Similarly, the proliferative effect of substance P on T and B cells is common knowledge. The supportive effect of norepinephrine on antibody production has been demonstrated many times.^{20,136,138} These dichotomous effects of norepinephrine shape the immune response induced by T helper type 1 or type 2 priming antigens or autoantigens.

Catecholamine effects depend on the stage of T or B cell activation because naïve cells are influenced in different ways as compared with mature antigen-selected cells. Thus, timing of the neurotransmitter influence is mandatory. In addition, it is not clear how these neurotransmitters/neuropeptides act on the effector or tolerant version of T cells or B cells. Conflicting data exist on effects of norepinephrine on CD4⁺CD25⁺FoxP3⁺ regulatory T cells, and data for aggressive/regulatory B cells are not known. The present stage of knowledge does not really allow us to make a final statement as to how the sympathetic nervous system in secondary lymphoid organs supports aggressive or regulatory T and B cell responses. Experiments of the 1990s did not separate effects on aggressive or regulatory immune cells.

In summary, effects of the sympathetic nervous system depend on the given immune stimulus and on whether a T helper type 1 or type 2 cell response or involvement of B cells is prevailing. Many in vitro and in vivo studies indicate that norepinephrine supports the T helper type 2 cell immune response and the B cell response, but it suppresses the T helper type 1 cell response. Substance P, on the other hand, does not demonstrate such a dichotomy. For acetylcholine, acting through many receptor subtypes, detailed immunologic experiments have not been performed.

Resolution of Inflammation and Tissue Repair

Upon clearance of a pathogen, resolution of inflammation or reconstitution of normal tissue is the final step. Inflammation often leads to a preponderance of sensory nerve fibers (sensory hyperinnervation) over sympathetic nerve fibers, which are reduced in inflamed areas.¹¹⁵ In acute wounds, both nerve fibers disappear, but reappearance of sensory nerve fibers seems to start earlier than reinnervation with sympathetic nerves (Table 29-2).^{31,116,117,139-150} In general, reinstallation of sympathetic nerve fibers is a very long process, as substantiated in transplanted organs (>4 weeks), after tibial nerve crush (8 to 12 weeks), after chemical sympathectomy in the spleen (3 to 8 weeks), and after monophasic arthritis (4 to 8 weeks).¹⁵¹⁻¹⁵⁴

In a typical wound reaction, substance P promotes wound healing responses, and catecholamines have negative and positive effects on wound healing, such as inhibition of

Table 29-2 Behavior of Nerve Fibers and Their Neurotransmitters/Neuropeptides in Wound Reactions*

Nerve Fiber Type	Change during Wound Reactions	References
Sensory nerve fibers	Sensory nerve fibers are lost after 2 days but reappear after approximately 7 to 14 days	266-268
	Substance P and calcitonin gene-related peptide promote wound healing	269-273
Sympathetic nerve fibers	Fast loss of sympathetic nerve fibers and reappearance after approximately 14 days	274
	Catecholamines block wound repair via β -adrenoceptors	275, 276
	Norepinephrine inhibits wound macrophages and neutrophils	277, 278
	Catecholamines support later re-epithelialization	279-282
	Adenosine supports the wound healing response via A2 receptors (mediated through increase in fibrosis)	283, 284

*Experiments with 6-hydroxydopamine, the sympathetic nerve fiber toxic substance, are not included because this substance affects not only sympathetic nerve fibers.

wound macrophages/neutrophils but support of later re-epithelialization (see Table 29-2). Moreover, stressful events that release sympathetic neurotransmitters and glucocorticoids lead to wound healing problems.^{155,156} From this point of view, a preponderance of substance P–positive nerve fibers over sympathetic nerve fibers would be favorable. Sensory hyperinnervation is probably supportive.

CHRONIC INFLAMMATORY DISEASE

Neuronal Influences on Chronic Inflammatory Disease in Animal Models

Chronic inflammatory disease occurs when inflammation fails to resolve and tissue repair is inadequate. The neuronal elements can contribute to this process. Most studies investigated the role of the sympathetic nervous system in the adjuvant arthritis model in Lewis rats.¹⁵⁷

The proinflammatory role of substance P and sensory nerve fibers in this model was demonstrated early in the 1980s.¹³⁹ Additionally, substance P is proinflammatory for human synoviocytes and monocytes.¹⁵⁸ Nociceptive fibers in the draining dorsal lymph nodes must play a critical role during this induction phase because local capsaicin treatment of these lymph nodes markedly decreases disease severity.¹⁵⁹ Although the proinflammatory effects of substance P and other tachykinins are widely known, substance P–antagonistic therapies were not effective; this is probably a result of the redundancy in the tachykinin system.

In experiments conducted to study the role of the sympathetic nervous system in adjuvant-induced arthritis, most studies focused on a period of 14 to 40 days. From these studies, it is evident that overall peripheral sympathectomy or blockade of adrenoceptors (particularly via β -adrenoceptors) before or at the time of injection of Freund's adjuvant diminishes the severity of joint inflammation during the entire observation period of 40 days.^{160,161} Similarly, the sympathetic nervous system plays an aggravating role in the collagen-induced arthritis (CIA) model, which is an autoantigen-driven chronic inflammatory disease. This might result from increased CD4⁺CD25⁺FoxP3⁺ T cells, as was recently demonstrated.¹⁶² When the sympathetic nervous system was destroyed before immunization and up to day 18 after immunization, sympathectomy markedly reduced the severity of arthritis.^{162,163} However, when the sympathetic nervous system was destroyed after outbreak of the disease, sympathectomy strongly aggravated arthritis.¹⁶³

The surprising dual role of the sympathetic nervous system might be explained as follows. In the very early induction phase after injection of adjuvant/antigen, mobilization, migration, and chemotaxis of proinflammatory cells such as neutrophils, NK cells, and monocytes directed to the site of adjuvant/antigen injection play a dominant role. In addition, targeted destruction of sympathetic nerves in secondary lymphoid organs supports antigen presentation and the switch to an aggressive effector immune response.¹⁶¹ Under conditions with sympathectomy in secondary lymphoid organs, arthritis becomes more severe owing to improved antigen presentation, stronger T helper lymphocyte type 1 immune reactions (aggressive phenotype for tissue-specific autoantigens), and probably downregulation of several regulatory elements such as IL-4 and IL-10 (see phase 2).¹⁶¹ Because the effect of prior sympathectomy is long lasting, these initial events are important for later inflammatory disease, which has also been demonstrated in atopic dermatitis and experimental colitis.^{164,165} However, in the chronic phase of the disease, the influence of the sympathetic nervous system largely changes.

One of the main changes is loss of sympathetic nerve fibers in inflamed tissue and in secondary lymphoid organs, as was already discussed (phase 2, Figure 29-5). Nerve fiber loss, starting with onset of disease,^{117,118,166} turns the essentially anti-inflammatory influence of sympathetic neurotransmitters at high concentrations into a proinflammatory influence at low concentrations (see Figure 29-5). In addition, recently described tyrosine hydroxylase–positive cells with anti-inflammatory capacities appear in lymphoid organs and arthritic tissue.¹⁶⁷⁻¹⁶⁹ In chronic inflammatory disease, the number of these cells in secondary lymphoid organs increases over time, and they appear shortly after disease outbreak in the inflamed joint.¹⁶⁹ Because these cells can be eliminated by 6-hydroxydopamine treatment (the sympathectomy technique), the anti-inflammatory influence of these cells is soon lost after experimental chemical sympathectomy.¹⁶³ Loss of tyrosine hydroxylase–positive cells probably leads to an overall proinflammatory situation, because these cells might have tolerogenic activities.¹⁷⁰ The quite different effects of this sympathectomy tool are now explained by early destruction of sympathetic nerve fibers, which are proinflammatory (phase 1), and later destruction of anti-inflammatory catecholamine-producing cells in phase 3, which are anti-inflammatory.

Finally, the influence of the parasympathetic nervous system has attracted increasing interest. The $\alpha 7$ subunit of the nicotinic acetylcholine receptor is especially

relevant in the regulation of inflammatory responses¹⁷¹; this led to the concept of the cholinergic anti-inflammatory reflex. Additional experiments with agonists of the $\alpha 7$ subunit of the nicotinic acetylcholine receptor demonstrated the anti-inflammatory importance of this cellular pathway in animal experiments and human cells.¹⁷²⁻¹⁷⁸ It is important to note that this particular nicotinic receptor is highly expressed on macrophages and fibroblasts of patients with RA.^{175,177}

At the moment, it is unclear how the vagus nerve influences synovial inflammatory disease. Four different possibilities exist regarding how favorable cholinergic effects on joint inflammation can be explained: (1) The cholinergic influence supports sympathetic inhibition of splenic proinflammatory immune responses, (2) the cholinergic influence directly affects cells in draining lymph nodes of the trunk, (3) the cholinergic influence affects cells in the gut (which play an important role as substantiated in the HLA-B27 rat model of arthritis), and (4) nonneuronal acetylcholine release appears within inflamed synovial tissue.^{118,178,179}

Neuronal Influence on Endothelial Cells and Angiogenesis

Angiogenic effects of sympathetic neurotransmitters have been demonstrated in tumor models and in tumor cells. Because tumor cells often demonstrate quite different signaling pathways, generalizability of these findings for different forms of inflammation might be critical. Nevertheless, studies in this field are the only source of information. Norepinephrine has been implicated in angiogenesis by inducing vascular endothelial growth factor (VEGF) expression in tumor cells via β -adrenergic effects, while direct trophic effects on endothelial cells were demonstrated via $\alpha 1$ -adrenergic effects.¹⁸⁰ These effects were potentiated by hypoxia. In addition, the sympathetic co-transmitter neuropeptide Y (NPY) has angiogenic activities shown in animals deficient in the NPY receptor type 2. It is important to note that dopamine via D2 receptors has universal inhibiting effects on angiogenesis.¹⁸⁰

As long as sympathetic nerve fibers are present, α - and β -adrenergic and NPY effects are possible. When nerve fibers are lost, these typical effects of sympathetic neurotransmitters/neuropeptides can be expected only in border areas along the demarcation line in Figure 29-5 with still existing normal innervation, because tissue concentration would be high enough. In an area of lost sympathetic nerve fibers and replacement by catecholamine-producing cells, mainly α -adrenergic and dopaminergic effects predominate, because concentrations of norepinephrine are low and dopamine is the main neurotransmitter produced.^{169,181} Thus, angiogenesis might be supported by sympathetic neurotransmitters in the healthy border zone of inflammation but not in the middle of the inflammatory zone. Nevertheless, in the sympathetic α -adrenergic zone, sensory hyperinnervation exists, so that higher levels of substance P can be expected.

Substance P was demonstrated to support capillary growth in vivo in a rabbit cornea model and in a rat sponge assay via NK1 receptors. In addition, substance P stimulates proliferation of different endothelial cell types.¹⁸² In vivo

experiments showed that endogenous substance P could be implicated in neoangiogenesis connected with inflammation.¹⁸² Thus, the two neurotransmitter systems of catecholamines/NPY and substance P probably influence angiogenesis in inflammation.

Neuronal Influences on Fibroblasts and Adipocytes

Sympathetic neurotransmitters modulate the function of fibroblasts by inducing proliferation, collagen gene and protein expression, and fibroblast migration via $\alpha 1$ -adrenergic receptors.¹⁸³⁻¹⁸⁶ In contrast, fibroblasts undergo increased apoptosis and autophagy via β -adrenergic signaling.^{187,188} In addition, norepinephrine induces secretion of IL-6, IL-8, and matrix metalloproteinase 2 from fibroblasts via β -adrenoceptors.¹⁸⁹⁻¹⁹³ Under conditions with an α -adrenergic zone due to nerve fiber loss (see Figure 29-5), one can expect proliferative responses of sympathetic nerve fibers on fibroblasts. This can support the fibrotic process in chronic inflammatory lesions.

The proliferative effects of substance P on fibroblasts are well documented. Substance P supports the growth-promoting effects of IL-1 in cultured fibroblasts.¹⁹⁴ These substance P effects were mediated through NK1 receptors.¹⁹⁵ In addition, substance P induces migration of human fibroblasts in vitro.¹⁹⁶ Although substance P demonstrates a proliferative effect on fibroblasts, CGRP has no similar role, but it stimulates fibroblast IL-6 secretion.^{197,198} In conclusion, establishment of an α -adrenergic zone together with sensory hyperinnervation induces a proliferative effect.

In recent years, adipocytes in the proximity of inflammatory lesions have gained enormous interest because of their proinflammatory activities.^{199,200} These fat cells might be important targets of neuronal influences to support the inflammatory process. Indeed, it is well known that the sympathetic nervous system via β -adrenergic pathways is instrumental in releasing energy-rich free fatty acids that are used by different immune cells as energetic substrates (recently reviewed in the context of chronic inflammation in Straub et al⁷⁹). It is important to note that the fat tissue in the proximity of inflamed lesions is perfectly innervated by sympathetic nerve fibers. Thus, norepinephrine is present in adequate amounts to stimulate lipolysis via β -adrenoceptors (see Figure 29-5). $\alpha 2$ -Adrenergic stimulation leads to inhibition of lipolysis.²⁰¹ Thus, the balance between lipolysis-promoting β -adrenoceptor activation and lipolysis-inhibiting α -adrenoceptor activation dictates the degree of lipolytic activity and provision of energy-rich free fatty acids to consumers. In addition, the sensory neuropeptide substance P supports proliferation and antiapoptotic pathways in fat depots that might contribute to the development of inflammatory fat accumulation, which has been demonstrated in vitro and in vivo.^{202,203}

Neuronal Influences on Osteoclasts and Osteoblasts

Neurotransmitters of the sympathetic nervous system (catecholamines) and neuropeptides (vasoactive intestinal peptide, substance P, and CGRP) play a role in normal bone homeostasis. It is very important to distinguish the

different phases of osteoblast and osteoclast differentiation because the influence of neurotransmitters/neuropeptides depends on the differentiation stage. Catecholamines inhibit bone formation via β_2 -adrenergic receptors by stimulating osteoclast differentiation and by inhibiting osteoblast function.²⁰⁴⁻²⁰⁶ This can be opposed by agonists of α -adrenoceptors.^{207,208} Because noradrenaline has a higher binding affinity for α -adrenoceptors than for β -adrenoceptors, the local concentration of this neurotransmitter most probably determines the effect (low concentrations can support bone formation, high concentrations inhibit bone formation).

Vasoactive intestinal peptide and CGRP support bone formation by inhibiting osteoclastogenesis and by stimulating osteoblasts^{209,210}; this is different for substance P, which preferentially stimulates osteoclasts and thus bone resorption.^{211,212} All these mechanisms have been detected in cells of healthy subjects or normal animals and/or in cell lines. No such studies have been carried out in primary osteoblasts or osteoclasts from arthritic animals or patients with arthritis. This must be the subject of future studies because in chronic inflammation, the situation might be quite different.

CHANGES OF THE NERVOUS SYSTEM IN PATIENTS WITH CHRONIC INFLAMMATORY DISEASES

Increased Activity of the Sympathetic Nervous System

Several studies have demonstrated that patients with chronic inflammatory diseases have an elevated sympathetic nervous system tone.²¹³⁻²¹⁶ Increased sympathetic activity could be related to increased risk of cardiovascular events, as has been observed in patients with RA.²¹⁷ Such an increased sympathetic tone may be a consequence of relatively decreased serum levels of cortisol in relation to inflammation, because there exists cooperativity of cortisol and norepinephrine on a molecular level via the β -adrenergic receptor signaling cascade.^{218,219} Functional loss of one factor probably upregulates the other factor to maintain functions such as blood glucose homeostasis, regulation of the bronchial lumen, blood pressure control, and others. Because TNF is relevant for adaptation of the HPA axis leading to inadequately low cortisol secretion, its neutralization may change the increased sympathetic tone.

A recent study confirmed increased sympathetic tone in patients with RA and also in those with SLE; this was accompanied by relatively normal tone of the HPA axis (called "uncoupling of the HPA axis and the sympathetic nervous system" during chronic inflammation because an increase in the tone of both axes can be expected during acute inflammation).²²⁰ It was found that 12 weeks of anti-TNF therapy only slightly decreased sympathetic activity as measured by plasma neuropeptide Y levels.²²⁰ Thus, uncoupling persists after treatment, and it appears that TNF is not the sole factor responsible for this phenomenon. A similar increase in sympathetic activity has been demonstrated in patients with Crohn's disease and ulcerative colitis.²²¹

It should be mentioned that elevated activity of the sympathetic nervous system might not cause increased

local sympathetic neurotransmitters in the inflamed joint because sympathetic nerve fibers are lost.¹⁶⁷ In addition to increased sympathetic nervous tone, one observes a decrease in parasympathetic outflow.⁸³ Such a decrease in the parasympathetic system is probably an unfavorable signal because this will impede the anti-inflammatory activity of the vagus nerve.²²²

Loss of Sympathetic Nerve Fibers and Sprouting of Sensory Nerve Fibers

Loss of sympathetic nerve fibers and sprouting of sensory nerve fibers have already been described in Figure 29-5. Loss of sympathetic nerve fibers has been described in the synovial tissue of patients with RA,^{167,223-225} in the oral mucosa of patients with lichenoid reactions,²²⁶ in the inflamed Charcot foot,²²⁷ in inflammatory endometriosis,²²⁸ in chronic pruritus and prurigo nodularis,²²⁹ in Crohn's disease,¹⁶⁵ and in other cases. Sprouting of substance P-positive sensory nerve fibers has been observed in gastritis,²³⁰ esophagitis,²³¹ and psoriatic skin disease,²³² and in the synovial tissue of patients with RA compared with osteoarthritis,²²⁵ Charcot foot,²²⁷ chronic pruritus and prurigo nodularis,²²⁹ Crohn's disease,¹⁶⁵ and other conditions. A marked preponderance of substance P-positive nerve fibers over CGRP-positive nerve fibers has been noted in RA synovial tissue; this supports inflammation in that CGRP would have some anti-inflammatory properties.²³³ Generally, all these findings support the concept of a nonspecific reaction that favors inflammation.

This concept is supported by additional results indicating that in later stages of inflammatory joint disease, α_1 - and α_2 -adrenergic receptors seem to gain a more prominent role. In patients with juvenile chronic arthritis, functional α_1 -adrenergic receptors on leukocytes are induced, whereas the receptors are absent on the leukocytes of normal donors.¹⁵ These effects seem to be cell type specific in that vascular α -adrenergic receptor-mediated vasoconstriction in inflamed joints is downregulated, leading to elevated perfusion.^{234,235} Suppression of α -adrenergic receptors on vasoconstrictors and parallel induction on leukocytes would serve as a proinflammatory stimulus because this leads to vasodilatation (vessels), proliferation of lymphocytes, and secretion of proinflammatory cytokines such as IL-6 and TNF (leukocytes).

AP-1- and NF κ B-binding sites are present in the regulatory region of the α_1 -adrenergic receptor promoter that may be responsible for the induction of α_1 -adrenergic receptor expression in monocytes by IL-1 β and TNF.²³⁶ In another study, synovial fibroblasts of patients with RA could be activated to proliferate by α_2 -adrenergic agonists; this process is mediated via phospholipase C, protein kinase C beta II, and mitogen-activated protein (MAP) kinase.²³⁷ Ex vivo studies with peripheral blood mononuclear cells from RA patients revealed that only in patients with high disease activity did catecholamines mediate their effects via α -adrenergic receptors.²³⁸ In addition, peripheral blood mononuclear cells of patients with RA demonstrate lower numbers of β -adrenergic receptors, supporting the overall α -adrenergic preponderance.¹⁶

From these data, it seems as though α -adrenergic signaling becomes more relevant in the later stage of this chronic

inflammatory disease. This is referred to as the “beta-to-alpha-adrenergic shift” during disease progression (see Figure 29-5).²³⁹

Cells Positive for Neurotransmitters/Neuropeptides Appear in the Tissue

In recent years, several reports have described the presence of immune cells in inflamed tissue with the capacity to produce neurotransmitters or neuropeptides. These studies demonstrated the production of substance P from RA and osteoarthritis synovial fibroblasts.^{240,241} Production of this neuropeptide was linked to a proinflammatory situation.

RA fibroblast-like synoviocytes and macrophages possess the enzyme machinery for catecholamines.¹⁶⁷⁻¹⁶⁹ The production of catecholamines seems to exert anti-inflammatory effects in synovial cells of patients with RA.¹⁶⁹ Catecholamine production was linked to a tolerogenic phenotype of T lymphocytes in patients with multiple sclerosis.^{170,242} Cells in inflamed lesions can also secrete endogenous opioids with anti-inflammatory activities.²⁴³ Even the production machinery for acetylcholine exists in cells of the synovial tissue and might also be an anti-inflammatory signal.¹⁷⁹

The role of these cells is not clear, but it seems that the anti-inflammatory activities of catecholamine-, opioid-, and acetylcholine-producing cells are insufficient to overcome the proinflammatory domination. It needs to be investigated whether a change in neurotransmitter/neuropeptide secretion can be achieved by therapeutic drugs, leading to higher production of anti-inflammatory neurotransmitters/neuropeptides.

SUMMARY

Various neuronal systems exhibit both proinflammatory and anti-inflammatory roles, depending on many influences: (1) time point in relation to the start of the inflammatory process, (2) antigenic stimulus shifting the immune response, (3) tissue location and environment, (4) involved cell types and time-dependent receptor expression, (5) changing tissue innervation, and (6) appearance of neurotransmitter-producing cells. Thus, the general statement of “the neuronal anti-inflammatory reflex” is meaningless outside this context.

Three decades of experimentation and clinical investigation have demonstrated the proinflammatory role of the nervous system in chronic inflammatory disease (sensory vasoregulation, peripheral and central sensitization, neurotransmitter-induced chemotaxis and cell mobilization, sympathetic nerve fiber loss, sensory hyperinnervation, etc.). As the result of adaptive programs, the net effect is unfavorable in chronic inflammatory diseases with immunity against self-antigens or harmless foreign antigens. Unfortunately, many anti-inflammatory activities of the different nervous systems are switched off (β -adrenergic, adenosinergic, opioidergic, cholinergic, and others). Therapeutic targets that capitalize on the anti-inflammatory effects of the nervous system or neurotransmitters have considerable potential to modulate chronic inflammatory diseases.

Principles of Epidemiology in Rheumatic Disease

YVONNE M. GOLIGHTLY • JOANNE M. JORDAN

KEY POINTS

Epidemiology is the study of the distribution of disease and its determinants in populations. Epidemiologic methods can describe the frequency or development of disease and to determine underlying causes.

Prevalence is the frequency of disease in the population at a given time including both existing and new cases. Incidence measures the development of disease over time in a population initially free from the disease.

The odds ratio compares the odds of disease in an exposed population with that in a population without the exposure or risk factor under study. The relative risk is the risk of developing a disease over time in an exposed population compared with an unexposed population. In many instances the odds ratio can estimate the relative risk.

Threats to the validity of a study include chance, systematic bias, and confounding. Confounding occurs when an extraneous factor, related to both the exposure of interest and the disease but not part of the causal pathway between exposure and disease, is superimposed on the true risk factor/disease relationship.

Case-control studies examine exposures in a population that already has the disease under study and compares them with exposures in otherwise comparable individuals without the disease derived from the same source population. This study design may be subject to recall bias, in which patients with a disease report exposure to risk factors differently than those without the disease, but it might be the design of choice for rare diseases.

Cohort studies follow groups of individuals with and without an exposure of interest for the development of disease over time. Because the exposure assessment precedes the disease, temporality can help determine causation.

Controlled clinical trials most closely resemble formal experiments in which the exposure is manipulated by the investigator, and the response of disease is compared between groups that receive the active intervention and groups that receive a placebo or other comparator.

OVERVIEW OF EPIDEMIOLOGIC METHODS

Epidemiology is the study of the distribution of disease and its determinants in populations.¹ Its purpose is to describe the frequency of disease and to determine causes responsible for variation in disease occurrence. Comparison of the relative strengths of those causes and assessment of their generalizability can allow “truth” to be inferred. This chapter explains basic epidemiologic concepts and definitions; describes the major study designs, their strengths and weaknesses, and their usefulness in inferring causality; and demonstrates specific applications of these principles to the study of rheumatic diseases. For the purposes of this chapter, the term *disease* is used to represent a disease, death, or other health outcome of interest, and the term *exposure* is used to represent a risk or protective factor examined for its association with disease.

Measures of Disease Occurrence

Prevalence

The frequency of a disease in a population at any given time is its prevalence. It is measured at one point in time and is the proportion of individuals with a disease out of the total population under study. Importantly, the numerator makes no distinction between new and established cases of disease. Multiple estimates of prevalence over time are commonly used to determine trends in disease occurrence or need for health services.

Incidence

In order to determine the likelihood that disease will develop over time, repeated observations of the same people are required to determine who develops disease and who does not. Incidence proportion, or risk, is the frequency of new cases over a specified time, out of those at risk for, but without, the disease at baseline. During the observation period, a person may be at risk for the disease but not develop it, and he or she would contribute time at risk for the entire period. Alternatively, a person may develop the disease in question, die from competing risks, or be lost to

	YEAR											Total time at risk
	0	1	2	3	4	5	6	7	8	9	10	
Subject A	I					+						5.0
Subject B	I				X							4.0
Subject C			I								LFU	7.0
Subject D		I									LFU	4.0
Subject E			I							X		6.5
Total years at risk												26.5

Figure 30-1 Hypothetical calculation of person-time at risk for study of incidence of systemic lupus erythematosus over 10 years. I, beginning of observation period; +, died; X, developed disease; LFU, lost to follow-up. (Modified from Hennekens CH, Buring JE: *Epidemiology in medicine*, Boston, 1987, Little, Brown and Company.)

follow-up. All of these situations result in that person's no longer contributing time at risk to the denominator. The concept of person-time includes the actual time at risk contributed by each individual. For example, consider the hypothetical example of incidence of systemic lupus erythematosus (SLE) over a 10-year period (Figure 30-1). Person A may not develop the disease during the observation period but may die at Year 5 of a competing cause; this person contributes 5 person-years to the denominator. Person B might develop SLE 4 years after the study begins and thus is no longer at risk of developing the disease; this person contributes 4 person-years of time at risk to the denominator. Person C joins the study at Year 2 and is lost to follow-up at Year 9, contributing 7 years of time at risk. Person D joins the study at Year 1 and is lost to follow-up at Year 5 for a total of 4 years of person-time at risk. Person E joins the study at Year 2 and develops SLE halfway between Year 8 and Year 9, contributing 6.5 person-years at risk. Incidence rate is defined by the following²:

$$\text{Incidence rate} = \frac{\text{New cases developing over time period of observation}}{\text{Total person-time at risk for each individual without the disease at study entry}}$$

In the example, two new cases of SLE are observed and the total person-time from persons A through E at risk is $5.0 + 4.0 + 7.0 + 4.0 + 6.5 = 26.5$ person-years. Thus the incidence rate is 2 cases/26.5 person-years, or 1 case/13.25 person-years. This may be expressed as 0.0754 cases/person-year or 7.54 cases/100 person-years.

Measures of Effect

More important than just the description of frequency of disease or its development is the relationship between the disease and exposures to potentially causative factors. One way to examine this is to compare the prevalence or incidence of disease in groups with a given exposure compared with those without that exposure. Critical to the ability to

assess potential causality of an exposure/disease association is that the exposed and unexposed groups must be comparable. Measures to delineate this relationship between disease occurrence and exposure vary according to study design. Cross-sectional surveys and case-control studies use the odds ratio, which is a measure of the odds (prevalence odds = prevalence/1-prevalence; incidence odds = incidence/1-incidence) of disease in the exposed group compared with the unexposed group. Longitudinal designs can calculate a relative risk (ratio of risks) of the incidence of disease in the exposed compared with the unexposed groups.

STUDY DESIGNS

These include ecologic studies, cross-sectional surveys, case-control studies, cohort studies, and randomized controlled clinical trials—the last frequently considered the most rigorous study design and the one most closely representing a formal experiment. Each study design has its own inherent strengths and weaknesses (Table 30-1), and the choice of study design depends on the research question, the rarity of the disease under study, the availability of appropriate study and comparable control populations, resources available to conduct the study, and logistics.^{2,3}

Observational Studies

In observational studies the exposure is not randomly distributed in a population. The investigator *observes* the exposure rather than selects the exposure status of an individual.⁴ Types of observational studies include ecologic, cross-sectional, case-control, and cohort.

Ecologic Studies

In the ecologic study design, the unit of observation is a group, rather than an individual.⁵ Aggregate data on rates of disease and risk factors are compared to examine associations between disease frequencies and exposures. The ecologic study is frequently a design of expediency and can

Table 30-1 Common Epidemiologic Study Designs and Their Strengths and Weaknesses

Study Design	Definition	Measure of Effect	Strengths	Weaknesses
Ecologic	Aggregate data on exposures and disease; unit of analysis is a group, not an individual	Odds ratio	Inexpensive Short duration Hypothesis-generating	Susceptibility to confounding Ecologic fallacy
Cross-sectional survey	Data on exposures and disease obtained at one time from all individuals in an area (or a sample thereof) with and without disease	Prevalence Odds ratio	Can study several outcomes Short duration Can generate population prevalence estimates of disease and risk factor distributions	May not be able to determine whether disease preceded exposure Potential survivor bias Not practical for rare diseases Cannot produce incidence or relative risk estimates
Case-control	Study of exposure/disease relationship in cases with a disease and controls without that disease, who are selected from source population from which the cases arose	Odds ratio	Best for studying rare conditions or those with long latency Short duration Small sample* Inexpensive* Odds ratio can approximate relative risk	Inefficient for rare exposures Potential bias from sampling cases and controls separately May not be able to determine whether exposure preceded disease Potential recall bias Potential survivor bias Cannot produce prevalence or incidence estimates
Cohort	Individuals without disease are followed over time to determine which characteristics predict who will get the disease and who will not	Incidence Relative risk	Can determine sequence of events Less susceptibility to survivor bias and bias in measuring predictors Can study multiple outcomes Can generate population incidence, relative risk	Frequently requires large samples Not feasible for rare outcomes More expensive Long duration
Prospective	Study sample selected by investigator and followed forward in time for development of disease	Incidence Relative risk	Investigator control over selection of participants and measures	Increased expense Long duration
Retrospective	Study sample and measurement of exposures and disease over time have already occurred	Incidence Relative risk	Less expense Short duration	Less control over selection of participants and measures
Nested case-control	Case-control study within the context of a prospective or retrospective cohort	Incidence Relative risk	Underlying cohort design Relatively inexpensive, compared with measurement on entire cohort	May require bank of samples that can be assayed at later date until or after outcomes occur
Randomized clinical trial	Exposure (pharmaceutical, nonpharmacologic device, educational intervention) manipulated by investigator	Relative risk Hazard ratio	Most closely emulates an experiment Strongest design to produce evidence for cause and effect Random assignment of intervention minimizes confounding May be faster and cheaper for some study questions than observational studies	Costly in time and money Some research questions not suitable because of rare disease or ethical barriers May not be generalizable if highly controlled environment does not reflect "real world" common practice May have narrow scope and study question

*Relative to cohort study design.

Modified from Hennekens CH, Buring JE: *Epidemiology in medicine*, Boston, 1987, Little, Brown, and Company; and Hulley SB, Cummings SR: *Designing clinical research: an epidemiologic approach*, Philadelphia, 1988, Williams & Wilkins.

generate hypotheses for more rigorous testing in studies using individual-level data.³ One of its chief drawbacks is its high susceptibility to confounding. This occurs when an extraneous factor, not on the causal pathway, masks the true relationship between exposure and disease, by virtue of its association with both.⁶ Further, associations in the aggregate may not necessarily hold for the individual.³ This concept is termed the *ecologic fallacy*. As a hypothetical example, rates of specific kinds of cancers may be higher in countries in which cigarette sales are also high. Whether those who are buying, and presumably smoking, the

cigarettes are the same persons who develop cancer is not known from this study design.

Cross-Sectional Surveys

The goal of this study design is usually descriptive including all individuals, with and without the disease under study, in the population or a representative sample of them, at one point in time with no follow-up period. Surveys can estimate prevalence of a particular disease in the population and determine the need for health services and resource

allocation.³ Typically, information about risk factors is obtained simultaneously. Such risk factor data may or may not represent the most relevant time of exposure, nor can it be determined whether the exposure preceded or resulted from the disease.²

An example of a cross-sectional survey, conducted approximately once per decade in the United States, is the National Health and Nutrition Examination Survey. This survey samples a proportion of the residents in the contiguous 48 states and measures various health outcomes and habits such as blood pressure, serum lipids, height, weight, smoking, and dietary intake. These surveys have been used in rheumatology to determine the prevalence of radiographic knee and hip osteoarthritis (OA) in various age, sex, and race/ethnicity subgroups.⁷

Case-Control Studies

Much maligned by the uninitiated because of its susceptibility to bias, the case-control study can be the study design of choice—or sometimes the *only* appropriate study design—in certain situations, particularly when the disease under study is rare. Usually, it includes fewer individuals—at much lower cost and higher efficiency—than would be required for a cohort study because it begins with individuals who already have the disease in question, rather than waiting for a small proportion of a large cohort to develop the disease over time. Most important in the design of a case-control study are (1) the choice of the control group, which must be comparable to the cases, and (2) recognition of potential biases that may threaten validity.

Strictly defined, the case-control study is a study in which those with the disease (cases) are compared with a control population without the disease, *drawn from the same source population from which the cases arose*.^{1,6} The source population may be the residents of a particular geographic area or a hospital's referral base. The control group serves as an estimate of the distribution of the exposure in the source population, and consequently, the control group must be sampled *independently of exposure* status.^{1,6} For example, if one is interested in examining the possible association between smoking and progressive systemic sclerosis (PSS), the controls must be from the same source population that generated the cases, if this can be determined, and must be sampled without regard to their smoking status.

Selection of Controls for Case-Control Study

If the source of the cases is a well-defined population, the controls can be sampled directly from that population. If the source population is too large to allow a complete enumeration, controls may be matched to each case by their residence in the same neighborhood. Random-digit dialing can be used to select controls, but this labor-intensive method omits from selection those without telephones or those who cannot be reached.¹ If the cases are drawn from a particular hospital or clinic, then the source population should represent people who *would be treated* in that hospital or clinic if they developed the disease under study, but frequently, this source population can be difficult to identify

and is influenced by referral practices.¹ Hospital or clinic controls can be used, but this method can have particular pitfalls because the controls might not be selected independently of the exposure in the source population. For instance, in a hospital-based study of smoking in SLE, individuals hospitalized for other diseases such as myocardial infarction or pneumonia might have exposures different from the source population in general, especially if the exposure, in this case smoking, causes or prevents the “control” disease selected. One way to avoid this is to exclude diseases known to be associated with the exposure under study, but this may create other biases. Another tactic could be to select hospital controls with diseases that are felt to be unrelated to the disease or exposures under study such as traumatic leg fractures¹ or to use several control groups selected differently.³ The latter example might sample controls from hospitalized patients with other diseases than the disease under study, nonhospitalized patients in the same medical care system, or nonhospitalized individuals in the general population, comparing each control group separately with the diseased group.

Weaknesses of the Case-Control Design

It is not possible to derive incidence or prevalence estimates from a case-control study. The greatest threat to validity is the inherent susceptibility to bias that can exist in this study design, because the cases and controls are sampled separately and the assessment of exposure variables is retrospective.³ Matching the cases and controls on factors such as age, sex, or race/ethnicity can help ensure comparability of cases and controls to a degree. As mentioned earlier, more than one control group, selected in different ways, can be used to see if findings are consistent across control groups with different sampling biases. A nested case-control design, in which a case-control study is performed within a larger cohort study, has the advantage of minimizing sampling bias because the cases and the controls would have been previously sampled in identical fashion into the parent cohort study.³

The other chief source of bias in the case-control study is recall bias, which occurs when exposures predating the disease may be differentially reported by the controls and the cases, the latter of whom may have incentive to remember and report exposures. This can be partially prevented by using exposure data measured before the disease occurred, if available, and by blinding the observer and the subject to the exposure under investigation or, if possible, blinding them even to the specific disease under study and therefore to case or control status. For example, in a case-control study examining racial/ethnic variation as the exposure variable of interest in SLE, race/ethnicity is immutable and therefore not subject to recall bias. In contrast, if study participants know or suspect that prior exposure to hair dye, for instance, is the exposure of interest in the same case-control study, those with disease may be more prone to “remember” their exposure than might those without disease. Investigators can obtain information about multiple potential exposures or even include several “dummy” exposures to mask the real hypothesis to try to minimize this type of bias.⁸

Cohort Studies

Cohort studies follow groups of individuals without the disease in question over time to describe the development or incidence of disease and to compare the incidence of disease among groups with different risk factors or exposures. Cohorts can be prospective or retrospective.^{1,3}

Prospective Cohort Study

Prospective cohorts are characterized by the selection of the cohort and measurement of risk factors or exposures *before* the outcome has occurred, thereby establishing time sequence or temporality, an important factor in determining causality. This is a distinct advantage over the case-control study in which exposure and disease are assessed simultaneously.

The primary disadvantage to the prospective cohort study is its expense, in that it requires large numbers of individuals followed for potentially long periods of time. Biases can creep in, particularly if there is significant loss to follow-up. This study design is highly inefficient and inappropriate to study rare diseases, but its efficiency increases as the frequency of the disease in the population increases.³ For example, a prospective cohort study would be inappropriate to study PSS because of its rarity but excellent to study a common condition such as OA.^{9,10}

Retrospective Cohort Study

In a retrospective cohort, individuals are followed over time, but the cohort selection and collection of data have already occurred, sometimes for a different purpose than the current disease under study. For example, a cohort of individuals with small vessel vasculitis seen at a particular hospital between 1990 and 1992 could be identified, and data regarding baseline serologies, physical examination findings, and biopsy results when the patients were first evaluated could be abstracted. Then examination of outcomes such as stroke or development of dialysis-dependent renal disease could be ascertained in 2000, by medical record review or by re-contact with the individuals so identified. Because exposure or risk factor assessment *precedes* assessment of outcome, this study design can establish temporality, as in a prospective cohort, and is less subject to recall bias that can plague case-control studies. By selecting the cases and controls from the same source population, this study design also avoids some of the selection biases of case-control studies in which the cases and controls are sampled separately. The retrospective cohort design is cheaper and more efficient than a prospective cohort, but because the data collection has already occurred, inferences from such a study are highly dependent on the quality, completeness, and appropriateness of the original risk factor assessments to study their association with the disease in question.³

Nested Case-Control Studies

These studies are case-control studies that occur within the context of a prospective or retrospective cohort and are particularly useful in the assessment of risk factor variables

that would be too expensive to measure on all members of the cohort.³ In this design, members of a cohort who have developed a particular outcome during the observation period are selected and compared with a sample of individuals within that same cohort who have not developed the outcome. Then, for example, stored biologic specimens from baseline may be assayed for an exposure of interest such as vitamin D level and compared between those who developed the disease and those who did not.

Registries

Individual occurrences of a disease can be obtained from multiple sources within a defined geographic area to form a disease registry. The data from these sources are linked to avoid duplication of cases. Registries may be based on population, hospitals, or clinics. Hospital- and clinic-based registries may identify potential participants for clinical research.^{4,5} Examples of registries collecting longitudinal population-based data on rheumatic diseases include the National Data Bank for Rheumatic Diseases (www.arthritis-research.org) and the Arthritis Internet Registry (www.arthritis.org/arthritis-internet-registry.php).

Clinical Trials

The study designs described previously in this chapter were all observational designs; there was no experimental manipulation of the exposure or outcome. Experimental study designs or interventions include clinical trials, field trials, and community intervention trials.⁵ Inferences from such trials of treatments assigned randomly to a large enough sample are much less likely to suffer from biases and other threats to validity than are observational designs. Randomization in theory should eliminate most confounding, although some variation in risk factors between the intervention groups may occur by chance and should always be ascertained and addressed in the analysis if necessary. The validity of conclusions from a clinical trial depends in part on the avoidance of loss to follow-up or participant dropout.

Clinical trials can be conducted for pharmacologic or nonpharmacologic interventions such as dietary, physical activity, assistive devices, or educational interventions. Trials can include single or multiple dosages of the study intervention, placebo controls, active comparator controls in which the intervention of interest is compared with another agent whose efficacy is known, and combinations of interventions. For example, the Glucosamine/chondroitin Arthritis Intervention Trial (GAIT) compared glucosamine hydrochloride alone, chondroitin sulfate alone, and the combination of glucosamine and chondroitin with placebo and with an active comparator, celecoxib, for their effects on symptoms of OA of the knee.¹¹ The Arthritis, Diet, and Activity Promotion Trial (ADAPT) was a nonpharmacologic intervention in which diet, exercise, and the combination of diet and exercise were compared with a control group.¹² Such nonpharmacologic trials may include an “attention control” in which the control group does not get the specific intervention of interest but does get at least a minimal amount of attention from the investigator because

it is known that even minimal contact with the participants in a study can improve outcomes.¹³

Optimally, to minimize bias, the study should be double-blind, in which the assignment of treatment is unknown to the participant and to the data collector evaluating the participant's response. A cross-over design is a within-patient design, which allows each participant to be his or her own control and receive either the active intervention followed by a "washout" period in which no active or inactive treatment is given, and then the control treatment, or vice versa. This design has some advantages, particularly in sample size requirements, but can be biased if there is a significant carry-over effect of the active treatment into the "control" observation period.⁵ Response to treatment may also differ depending on whether the active drug is received before or after the placebo or other comparator.¹⁴

Other important considerations in clinical trials are the selection and means of assessment of primary and secondary outcomes, which must be prespecified. Outcomes can include measures of disease modification, symptom modification, and frequency of side effects or other poor outcomes. Symptom modification trials are frequently of short duration and less expensive than disease modification trials, which are generally interested in longer-term outcomes. In trials of biologics for rheumatoid arthritis, for instance, effects on symptoms can frequently be measured in weeks to months, whereas effects on prevention or healing of radiographic erosions may require longer follow-up times.¹⁵ Similarly, disease modification trials in OA currently require large numbers of individuals followed for at least 2 years, predominantly because the metric of change in minimal joint space on knee radiographs is imprecise and can be fraught with measurement error.¹⁶ It is expected that outcomes based on magnetic resonance imaging, once validated, will be more sensitive, less subject to measurement error, and require smaller sample sizes and shorter observation periods to demonstrate an effective response.¹⁷

Other trial designs can apply interventions to entire communities or to health care workers with measurement of outcome in their patients. An example of the latter would be an educational intervention designed to increase physician prescription of physical therapy evaluation of all patients with knee or hip complaints. The physicians receive the intervention, but whether the physical therapy is prescribed or whether it improves patient symptoms is measured by assessing the patient.

Although clinical trials represent the "ultimate" study design closest to a controlled experiment, there are significant potential threats to its validity. One of the most important biases can occur when there is large loss to follow-up. In order to minimize this type of bias, every effort should be made to continue to obtain outcome information on *all* participants, even those who otherwise discontinue study assignment to therapy. Because all predictors of dropout cannot be known and because dropouts may differ from individuals who remain in a study in ways that cannot be controlled, conventional analyses of treatment status are likely confounded.⁵ Data may be analyzed in an intention-to-treat fashion, in which all randomized participants are analyzed as a member of the group to which they were initially randomized, regardless of whether they actually adhered to the group assignment, but this analytic method

tends to be biased because noncompliance leads to a misclassification of treatment status.⁵ One method for dealing with treatment noncompliance suggested by Mark and Robins¹⁸ includes making the assigned treatment a fixed covariate and received treatment a time-dependent exposure in a structural failure-time model. Completer, or "according to protocol," analyses are often also performed, in which only those who adhered to their assigned group treatment are included in the analysis. Prerandomization screening and run-in periods before randomization can help to avoid randomizing those unlikely to adhere to or complete the protocol, thereby minimizing expense and dilution of effects.^{19,20} Other issues to consider in the interpretation of results of clinical trials deal with generalizability and the difference between efficacy in a controlled environment and effectiveness in the real world of everyday practice. Postmarketing observations can often reveal side effects or unintended consequences of interventions that may not be apparent within the context of highly regulated trials. More detail regarding design of clinical trials can be found in Chapter 32.

Noninferiority Trials

A common type of randomized control trial is the *superiority trial*, in which investigators determine whether a new treatment is more effective than placebo, no treatment, a lower dose of the test treatment, or an established treatment that is widely used or that has known effectiveness. *Noninferiority trials*, on the other hand, are used to determine whether the effect of a new treatment is no worse than a reference treatment.²¹⁻²³ This differs from an *equivalence trial*, which aims to demonstrate that the effect of a new treatment is similar to the effect of the reference treatment.²¹

Designing and interpreting noninferiority trials can be challenging due to several weaknesses of this study compared with superiority trials. Intention-to-treat analysis (a commonly used approach in superiority trials in which not all participants may have completed the treatment protocol) is not possible in noninferiority trials. Intention-to-treat analysis tends to bias results toward the null (treatment equivalence), which, in a noninferiority trial, would result in an inferior treatment's being incorrectly labeled as noninferior.^{21,22} Additionally, an inferiority margin must be predetermined, and this margin may be subjectively based on the expectation of a minimally important effect or, more objectively, on the effect of the reference treatment in prior studies.^{22,23} For the latter, the assumption is that the effect of the reference treatment in the noninferiority trial is similar to its effect in prior trials, which may not be true if the current and prior trials differ on the basis of critical factors (i.e., study population).^{21,22}

Comparative Effectiveness Research

Evidence of effectiveness of treatments is necessary for informing medical decisions by clinicians, patients, and caregivers; reducing health care costs; and improving outcomes. Comparative effectiveness research (CER) generates evidence on the effectiveness of treatments with the goal of determining which treatment is best for particular groups of people with certain conditions to improve the quality of

treatments and outcomes.²⁴ Systematic reviews in which all results from existing studies are compiled and the benefits and risks of the treatments are evaluated across different populations may be conducted. Alternatively, new studies may be conducted to examine the effectiveness of a treatment including its benefits, side effects, and costs compared with other available treatments for a given outcome in a specified population.

The quality of health care has continued to improve over the past decade in the United States, yet the increasing costs and financial burden of health care, as well as regional differences in treatment use, cost, and outcomes, are concerning.^{24,25} For example, Fisher and colleagues²⁶ reported that individuals in the highest-spending regions received 60% more health care than the lowest-spending regions, but this additional care did not result in improved mortality rates, functional status, or patient satisfaction. The rising health care costs and distressing regional differences have given rise to a push for focused efforts on CER nationally. Under the American Recovery and Reinvestment Act (ARRA) of 2009, Congress allocated \$1.1 billion to spark the advancement of CER nationally to improve health care quality while reducing costs.²⁴ As required by the ARRA, the Institute of Medicine (IOM) Committee on Comparative Effectiveness Research Prioritization selected 100 health topics requiring CER including osteoarthritis (musculoskeletal disorders) and rheumatoid and psoriatic arthritis (immune system, connective tissue, and joint disorders) on the basis of the input of public and private stakeholders.²⁴ For additional information on the national priorities of CER, the IOM's *Initial National Priorities on Comparative Effectiveness Research* is available at the National Academies Press website: www.nap.edu.

Biases in Study Design

Error in a study may be random (chance) or systematic (bias). Bias includes errors in the selection of participants, errors in measurement of a variable, or confounding. Bias may produce an incorrect conclusion about the association between an exposure and disease.

Selection Bias

The procedures used to select participants for a study or factors related to study participation may result in a different exposure-disease association between participants and nonparticipants. Selection bias may occur in any study design, most notably in retrospective or case-control studies, where the exposure and outcome both occur before selection of participants. Differential participation may arise in cohort studies or clinical trials with loss to follow-up, particularly if participants leave the study for reasons related to the exposure or the disease.

Information Bias

Errors in the measurement or collection of information may occur. If a variable is measured categorically, information about a participant may be placed in the wrong category or misclassified. Nondifferential misclassification of an exposure occurs when misclassification is not related to

the presence of disease.¹ Misclassification is differential if exposure differs by disease status.¹ Likewise, misclassification of a disease is nondifferential if it does not differ by exposure status and differential if it varies by exposure status. Nondifferential misclassification biases an association between exposure and disease toward the null, except if the association is the null. Differential misclassification may bias the association in either direction.

Recall Bias

In case-control studies, those who are cases may have a different recall of their exposure history than those who are noncases. This difference in recall can introduce a bias that inflates the estimate of an association between exposure and disease. Recall bias is differential misclassification because the exposure is misclassified differently among cases and controls.¹ Methods for reducing recall bias include structuring questions to improve recall for both groups, selecting a control group that would be more likely to have good recall of exposure history, or using information other than interview such as medical records.¹

Confounding

Confounding occurs when there is a “mixing of effects” among the exposure, outcome, and a third factor.²⁷ Specifically, a confounding variable is a risk factor for the disease, is associated with the main exposure, and is not an intermediate step on the causal pathway from exposure to disease.⁵ For example, when examining leg length inequality as a risk factor for lower extremity OA in a cohort study, a likely confounding variable would be injury to the lower limb. Injury is a risk factor for OA, it is associated with leg length inequality (a severe injury to a lower limb can result in a shortening of that limb), and it precedes both OA and leg length inequality. Methods used to control confounding include stratifying data by the confounding variable or including the variable as a covariate in multivariable statistical models. Matching may reduce confounding in case-control studies. In experimental studies, randomization is a strategy for reducing confounding.

The amount of confounding is an important consideration in determining whether one should control for it in analyses.⁵ If the estimate of an association minimally changes after adjusting for a potential confounding variable (e.g., unadjusted odds ratio = 2.62, adjusted odds ratio = 2.58), the inclusion of the variable as a covariate in a multivariable model may not be necessary. However, if the estimate changes profoundly (e.g., unadjusted odds ratio = 2.62, adjusted odds ratio = 1.05), then methods to control confounding should be employed to reduce bias in the association.

EFFECT MEASURE MODIFICATION

Two factors are considered to be independent if the combination of their effects is equal to their joint effects. If the effect of one factor depends on the effect of another, effect measure modification exists. This concept is also known as *statistical interaction*. Examining effect measure modification allows for the investigation of whether the association

between exposure and disease differs across subgroups. For example, Krishnan and colleagues²⁸ reported a strong association between past history of smoking and RA in men (odds ratio 2.0, 95% confidence interval 1.2 to 3.2), but not women (odds ratio 0.9, 95% confidence interval 0.6 to 1.3). On further exploration, this association was only seen among men with rheumatoid factor–positive RA. If effect measure modification is not considered, results could be biased or important groups for targeting interventions could be missed.

SCREENING

Screening is an important public health strategy in reducing morbidity and mortality.²⁷ Screening tests classify a person who is asymptomatic as being likely or unlikely to have the disease. This differs from diagnostic tests, which determine whether a person with signs or symptoms of a disease truly has the disease. If a screening test suggests a high likelihood of disease, then further diagnostic evaluation may occur to confirm disease presence. Although not applicable in all diseases, the early detection of disease when a person is asymptomatic is felt to result in more effective treatment than if disease detection occurs later when symptoms develop with advanced disease.²⁷ To determine the validity of a screening or diagnostic test, one must establish the sensitivity or specificity of the test. Often, a new test may be compared with a “gold standard” of the definition of a disease, although this standard may not encompass all signs and symptoms of that disease. For example, biologic markers may be useful screening tools for detecting early changes in joint health that lead to OA. The presence of radiographic features of OA may be used as a comparative “gold standard,” yet this definition of OA lacks other components used to diagnose the disease such as pain, aching, or stiffness in the joint.

Sensitivity

Sensitivity is the probability that a test will *correctly classify a case*. This is expressed as a proportion of the number of cases identified by the test out of the total number of individuals with the disease. In screening, sensitivity is the probability of correctly classifying an individual as a detectable, preclinical case. If a test correctly provides a positive test result for 37 out of 43 people with disease, the sensitivity of the test is 86% (Table 30-2).

Specificity

Specificity is the probability that a test will *correctly classify a noncase*. This is expressed as a proportion of the number of individuals without disease identified by the test out of

the total number of individuals without disease. If a test correctly provides a negative test result for 62 out of 66 people without disease, the specificity of the test is 94% (see Table 30-2).

Predictive Value

Predictive values are used to interpret the results of a test by examining the correct classification of individuals by the test. This measure is valuable because whether a person is truly a case or noncase is difficult to know (for determining sensitivity or specificity), but a positive or negative result of a test is known. A *positive predictive value* is a proportion of the number of cases identified out of all positive test results. If 37 people truly have disease out of 41 with a positive test result, the positive predictive value is 90% (see Table 30-2). A *negative predictive value* is a proportion of the noncases identified out of all negative test results. If 62 people truly do not have disease out of 68 with a negative test result, the negative predictive value is 94% (see Table 30-2).

SUMMARY

Epidemiologic methods can be used to measure frequency or development of disease and evaluate risk or protective factors in disease occurrence. Choice of study design depends on multiple factors including the research question, disease under study, availability of appropriate study populations, and resources available. Each study design has its own set of advantages and disadvantages, with the clinical trial considered the most rigorous.

KEY POINTS

Studies of the economic burden of diseases are especially helpful in allocation of health care resources for musculoskeletal conditions in which mortality rates are less prominent.

The economic burden is enumerated by summing expenditures for medical care, termed “direct costs,” and earnings losses and value of productivity losses in other activities, termed “indirect costs.”

Per-person direct costs of musculoskeletal conditions have risen by more than 25% over the past decade, to \$6799 in 2007 dollars.

Much of this increase is fueled by a 50% increase in the number of prescription medications used each year by persons with musculoskeletal conditions and by a 38% increase in the price per prescription.

Per-person earnings losses have risen by almost 50% during the same time, to \$4979 in 2007 dollars.

Whites, non-Hispanics, and the insured experience substantially higher medical care costs than members of minority groups and those without insurance, suggesting that substantial disparities in access to care continue in the United States.

The aggregate economic impact of musculoskeletal conditions in the United States has increased by about 30% over the past decade, from the equivalent of 5.6% to 7.3% of the gross domestic product.

The increasing use of biologic agents for rheumatoid arthritis has led to a rapid increase in the direct costs associated with this condition; costs of these agents alone exceed the total costs of RA from the prebiologics era including direct and indirect costs.

Cost-of-illness studies are used to provide a measure of the impact of medical conditions and can overcome the natural tendency of policymakers to focus attention on those conditions with high mortality rates to the exclusion of those with a high impact on quality of life.

Studies of the economic impact of musculoskeletal conditions as a whole have been conducted since the early 1960s using a mélange of publicly available data sources. Such studies indicated that over 3 decades, the economic impact of musculoskeletal conditions increased from the equivalent of about half a percent of the U.S. gross domestic product (GDP) to more than 2.5%. Over the past decade, the availability of a well-designed individual data source in the United States, the Medical Expenditures Panel Survey,

Economic Burden of Rheumatic Diseases

EDWARD YELIN

has permitted researchers to estimate the economic impact with greater precision and to show that over that decade alone, the economic impact increased by the equivalent of more than 1.5 percentage points of GDP, to more than 7%. In the Great Recession that began in 2008, GDP declined by about 7%, so the economic impact of musculoskeletal conditions can be said to approach the same level as that of the Great Recession, although the effect is chronic, not acute.

There is now a substantial literature on the economic impact of rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and osteoarthritis (OA). The studies in this literature are largely based on clinical samples, most from tertiary care centers, and indicate that there are substantial costs associated with all three conditions; this was so for RA even before the development of biologic agents. The most recent studies of RA indicate that with the advent of these agents, the costs of RA have skyrocketed, with the costs due to the biologic agents alone eclipsing the total costs of RA before their development including all other medical care costs and all wage losses.

The economic burden of musculoskeletal conditions is rapidly increasing in developing nations. Each discipline may use different tools to assess the burden of disease. Rheumatology health professionals may measure the impact of these conditions in terms of the discomfort and disability they cause and that these professionals may alleviate by providing health care. Psychologists may measure the impact of musculoskeletal conditions on the achievement of mental equipoise, or its opposite, mental discomfort. Economists take the measurements provided by other disciplines and turn them into monetary equivalents to describe the magnitude of the burden associated with musculoskeletal conditions. Thus economists are concerned with the monetary value of the resources used to produce health and with the return on the use of those resources in terms of reduced impacts of illness on pain and functioning. Cost of illness is an accounting of the resources spent in pursuit of health and of the residual amount of discomfort and disability left after those resources are spent¹⁻³ (Table 31-1).

Economics is far more than a positive science, that is a discipline that observes how things are rather than seeking to change them, however. The normative part of the discipline has dual and sometimes competing goals. The first of these is ensuring that resources are allocated equitably (i.e., making sure that they are distributed fairly across individuals). The second is to make sure that they are used efficiently (i.e., as well as contemporary technology permits to produce goods).⁷ In health, resources would be distributed equitably if persons with similar levels of health received relatively

Table 31-1 Principal Methods to Assess Costs of Illness

There are two principal methods to assess the costs of illness: (1) the human capital approach, developed by Dorothy Rice when she was at the Social Security Administration and later the National Center for Health Statistics,^{1,4} and (2) the willingness-to-pay approach.⁵ The two methods do not differ in the way that they assess the direct costs of medical care. For the indirect costs associated with loss of function and the intangible impacts of disease, the human capital approach uses the market value of the labor to reduce the impacts (e.g., by hiring a replacement worker). In a variant of the human capital approach called the “friction method,”³ the losses are estimated from the perspective of the employer and only last until the replacement worker is hired and then achieves the same productivity as the worker who left as a result of disease. At that point, an employer would be said to incur no additional costs from the onset of the prior incumbent’s disease. The willingness-to-pay approach values the loss of function as the amount the affected individual would pay to restore the function, which may be more, the same, or less than the amount it would take to replace the worker in the labor market. The human capital approach is no doubt more reliable in estimating the economic impact of the lost productivity of affected individuals because the cost of labor is well established in all advanced societies and, therefore, easy to estimate. The human capital approach, however, usually only enumerates the intangible impacts of disease (e.g., the burden associated with the experience of intense pain) but does not translate them into economic terms. The willingness-to-pay approach is theoretically capable of incorporating all of the costs of disease in those terms, although as a practical matter there are problems associated with attempting to do so.⁶

equal access to health care services shown to reduce the burden of disease and which, based on a thorough knowledge of the treatment options, they chose for themselves. Similarly, in health, resources would be used efficiently if they produced the health outcomes people wanted while leaving the maximum amount to be used for other purposes, what economists refer to as “the opportunity cost” of those resources.

The pursuit of equity and efficiency may work in harmony. If resources are used efficiently to provide health care, then more can be allocated to ensure that everyone has access to the same set of services they desire. But the opposite is also true: if resources are used inefficiently, then the “wastage” cannot be redistributed to ensure that everyone has equal access.

The evidence that the distribution of health care resources in the United States is inefficient has been increasing for several decades and comes from studies conducted within the United States⁸⁻¹⁰ and from those comparing the United States to other nations.¹¹⁻¹³ The inequitable distribution, however, has also recently become a central focus of analysis and policy. The signposts for inefficiency might be said to include the use of any test or procedure for which evidence has emerged, suggesting that the test or procedure does not work or does not work as well as alternatives that are available. Every comparative trial that does not result in a decreased use of the comparator that worked less well is, thus, evidence in support of the argument that our system of care is inefficient. However, the most compelling evidence comes from studies that compare populations of regions for the use of select tests and procedures and fail to find that those areas that use more of one achieve better health outcomes.¹⁴ Similarly, international comparisons

often show that the extra usage within the United States fails to improve health-related quality of life, let alone longevity in comparison with other nations.¹¹ Such studies also fail to show that the extra usage engenders greater satisfaction with most aspects of care.

The methods and data sources to estimate the economic burdens of disease, the positive side of health economics, have certainly improved over the years since the first cost-of-illness studies for the nation as a whole were completed by Dorothy Rice and colleagues. Subsequent to the development of the methods of cost-of-illness studies by Rice and others, individual investigators used those methods and the availability of clinical samples to provide highly specific estimates of discrete rheumatic conditions, particularly RA.¹⁵ For national estimates, the U.S. federal government has developed an annual survey, the Medical Expenditures Panel Survey (MEPS) to provide reliable estimates of the cost of illness experienced by individuals.¹⁶⁻¹⁸ The prior work by Rice relied on separate data sources about ambulatory care, hospital admissions, and nursing homes. The same individuals were not included in each of these data sources; indeed, the data sources were based on samples of medical care encounters rather than of individuals with specific conditions. MEPS provides estimates about every kind of health care for the same individuals and does so through systematic sampling of the U.S. population. For fairly rare conditions, because of the uniformity of data collected in each year, it provides the opportunity to merge multiple years of data so that sample sizes are sufficient to provide estimates of the cost of these conditions reliably.¹⁹ Similarly, the batteries of items to measure impact in each domain (e.g., the magnitude of the ambulatory care used) have been vetted through reliability studies comparing survey responses to medical records and billing information. The one aspect of cost-of-illness studies that cannot be replicated using MEPS concerns the indirect costs associated with mortality. Thus a full accounting of the costs of illness would include an estimate of the discounted present value of lost earnings among those who die prematurely. Although mortality rates are elevated for those with inflammatory rheumatic conditions,²⁰⁻²⁴ in general musculoskeletal conditions are not associated with dramatically higher mortality rates. Therefore the bias in estimates of the costs of these conditions using MEPS data is relatively small.

The comprehensive sampling and reliability of batteries notwithstanding, the findings from the studies of Rice and colleagues about all kinds of conditions in the nation as a whole and the studies about persons with discrete conditions in clinical samples stand the test of time. Thus the early and contemporary studies both highlight the effect of population dynamics, particularly the aging of the population; increase in the cost of care as a function of changes in the kinds of services provided and increase in the unit price of those services; and changing employment circumstances and attendant wage losses on the burden of disease experienced by persons with musculoskeletal conditions.¹⁹

The tools of the normative part of economics, not the subject of this chapter, have also evolved over time (Table 31-2). The tools are normative because they are based on the notion that certain levels of health care expenditures unnecessarily divert resources from other uses and that

Table 31-2 Economic Methods to Assess the Value of Health Interventions

Drummond and colleagues² provide a concise review of the methods to estimate the relationship between health care expenditures and the returns of these expenditures in terms of health-related quality of life including one of its domains, employment. When one cannot show that alternative levels of health expenditures will result in improved outcomes, one merely attempts to reduce the wastage of health expenditures, the subject of “cost-minimization studies.” When alternative treatments for a condition are available, one uses “cost-effectiveness analysis,” which shows the relative returns from these alternatives in a common natural metric (e.g., longevity). When one is comparing alternative investments across conditions, one needs an outcome metric that applies to all conditions equally; often the easiest outcome to measure in common terms is the dollar value of lost wages, the subject of “cost-benefit analysis.” However, there are inherent problems in translating outcomes into dollar terms. Accordingly, economists have developed such common metrics as the quality-adjusted life year, which takes into account the value individuals in society place on achieving a common outcome (economists use the term *utility* for these evaluations and use the term *cost-utility analysis* for assessing the returns on alternative health expenditures).

society should have allocative mechanisms, through the market or regulatory means, that redirect resources away from specific conditions or, more frequently, specific treatments for those conditions. That direct medical care expenditures for RA approach “x billion dollars” is a positive statement; that society should not be spending “y billion dollars” on specific treatments for RA is a normative statement; that a treatment achieves an end (e.g., extending life) less expensively than another, the product of a cost-effectiveness analysis, is a tool that may provide a guide in reallocating resources from RA care, in putting in place a policy to implement the notion that spending “y billion” on specific treatments for RA is not a good use of those resources.

This chapter summarizes the evidence accumulated on the current burden of musculoskeletal conditions overall, as well as on specific conditions within that overarching rubric. This is akin to indicating the temperature outside but not in indicating whether that temperature is hot or cold and thus whether the tools to assist in redirecting resources such as cost-effectiveness analysis should be used. However, as the evidence base in support of individual treatments for musculoskeletal conditions, for example, use of one or more disease-modifying agents in RA, or of entire strategies of treatment, for example, the use of both pharmacologic and behavioral interventions for OA increases, we as a society begin to have the means to move from the positive aspects of health economics to the normative.

STUDIES OF THE COSTS OF ALL FORMS OF MUSCULOSKELETAL DISEASE

In this section, data from the United States and elsewhere about the economic impact of musculoskeletal conditions as an entire category are presented. * Table 31-3 summarizes

information on health care utilization and medical care expenditures for persons with any form of musculoskeletal condition in the United States by averaging 3-year periods between the year in which the MEPS was initiated, 1996, and the last year for which complete data are available, 2007. Three-year averages smooth out individual discrepant values in any one year due to small sample sizes. The first triad of years, thus, incorporates data from 1996 through 1998, whereas the last incorporates data from 2005 through 2007. In the table, all costs are expressed in 2007 terms; all data, however, represent annualized figures. Between 1996-1998 and 2005-2007, there has been little change in the use of ambulatory or hospital care for persons with musculoskeletal conditions. In each triad of years, about 90% of such persons have one or more ambulatory visits and the average number of visits per person has increased only slightly, from 9.2 to 10.4 per year. Similarly, the proportion with one or more hospitalizations has remained relatively constant in the range of 11% to 12% a year, with the average number of admissions holding steady at 0.2 per person per year.

In contrast to ambulatory visits and hospital care, there has been substantial growth in the use of prescription medications. Between 1996-1998 and 2005-2007, the proportion with any use of prescription medications inched up, but the average number of medications per person increased by about 50%, from 13.1 to 19.6.

The second set of columns in Table 31-3 displays the change in the unit prices of each kind of service between the first and last 3-year periods. The unit price of ambulatory visits increased from \$185 in 1996-1998 to \$216 in 2005-2007, or by about 17% in real terms. Because we had previously seen that there was little growth in the average number of visits, this suggests that there may have been an increase in the intensity of services provided in ambulatory visits or improved reimbursement for similar services, or some combination of the two; MEPS data do not permit an analysis of the extent to which of these two factors contributed to the increase in the unit prices for ambulatory visits. There was relatively little change in the unit prices associated with hospital admissions among persons with musculoskeletal conditions, with unit prices of \$12,225 in 1996-1998 and \$12,129 in 2005-2007.

The third set of columns, per-person costs, is the product of the average number of units of services used and the unit prices. Total per-person costs increased by about 26% between 1996-1998 and 2005-2007, from \$5378 to \$6799. The overall increase was driven overwhelmingly by increases in prescription drug costs but with smaller contributions from ambulatory visits and hospital admissions. Prescription drug costs increased by more than 110% between 1996-1998 and 2005-2007 in constant dollars, from \$740 to \$1508. Ambulatory visit costs increased by a third during this time frame, from \$1694 to \$2256 while hospital costs held steady when taking normal variation in 3-year averages into account.

The data in Table 31-3 reflect all the medical care costs incurred by persons with musculoskeletal conditions, regardless of whether they were incurred for that set of conditions or other conditions. Another way to assess the cost of illness is to estimate the increment in total costs beyond those that would be incurred on behalf of persons just like those with musculoskeletal conditions but who do not actually have

*The results are based on the author's analysis of MEPS data. The methods were described in a 2001 publication²⁵ and replicated in subsequent publications.^{26,27}

From author's analysis of Medical Expenditures Panel Survey (MEPS), 1996-2007.

such conditions. There are two ways to make these estimates: by asking individuals to apportion health care episodes to various causes and by using regression techniques that take into account the health and demographic characteristics of the individuals because the attributions made by the individuals may not be reliable. Using the second method, approximately a third of the costs incurred by persons with musculoskeletal conditions can be attributed to those conditions.

The aggregate medical care costs associated with musculoskeletal conditions are the product of the costs per case, described in Table 31-3, and the number of persons with the conditions at any one time (Table 31-4). As can be seen in the table, the aging of the population is resulting in a substantial increase in the number of persons and percentage of the population with musculoskeletal conditions in the United States. Between 1996-1998 and 2005-2007, the number reporting one or more musculoskeletal conditions increased from 76.0 to 91.3 million, or by more than 20% in relative terms, while the percentage of the population with such conditions rose by 8.9% in relative terms, from 28% to 30.5%. When multiplied by the cost per person in each triad of years covered by the analysis, the aggregate costs rose from \$408.6 billion to \$620.9 billion in constant dollars, or by about 52% in relative terms. The dual importance of population aging and increases in the cost per case in the dynamics in the aggregate costs of musculoskeletal conditions can be seen by the fact that the percentage increase in the former, more than 20%, and the percentage increase in the latter, 26%, were both substantial.

The relatively large increase in the cost per case of all musculoskeletal conditions would have been even greater were it not for the fact that the vast majority of cases within the overall musculoskeletal diseases rubric are OA and similar mechanical diseases rather than such autoimmune conditions as RA or SLE. Treatments for OA, for example, have been relatively stable over time. As explained later, costs for individual autoimmune conditions have risen substantially over the past decade as new treatments such as the biologics for RA have taken hold.

Table 31-5 shows the per-person and aggregate medical care costs in 2005-2007, stratified by demographic characteristics. Musculoskeletal conditions are more prevalent

among females; females with the conditions also experience per-person medical care costs that are about 20% higher than men, \$7328 compared with \$6130. When the higher prevalence and higher per-person costs are combined, aggregate costs are \$373.2 billion among females and only \$247.6 billion among males, a difference of about 50%. Per-person medical care costs associated with musculoskeletal conditions increase monotonically with age, from a low of \$2994 among those younger than age 18 to a high of \$11,128 among persons 65 or older. However, because of the number of persons in the 45- to 64-year-old group, aggregate costs are actually slightly higher in the latter group than among those 65 or older, \$236.5 billion versus \$213.5 billion. Non-whites with musculoskeletal conditions experience slightly lower per-person costs than whites with these conditions, \$6436 versus \$6865, a difference of about 7%. On the other hand, Hispanics with musculoskeletal conditions incurred medical care costs of \$4969, fully 29% lower than the \$6981 incurred by non-Hispanics.

In addition to the differences by race and Hispanic status, there are substantial differences in medical care costs by a measure of socioeconomic status—extent of formal education. Those with less than a high school education experienced costs 18% higher than the next lowest group, those who had completed a high school education, probably reflecting the former group's greater need for medical care. Persons with musculoskeletal conditions who have never been married incurred substantially lower medical care costs than the currently or formerly married, 30% with respect to the former and almost 45% with respect to the latter.

Of note, persons with musculoskeletal conditions reporting public insurance actually incurred higher medical care costs than those with private insurance (\$9306 vs. \$6621, a difference of about 40%), but both groups had substantially higher costs than those without insurance who averaged only \$2304 per person in medical care costs, a difference of 65% relative to those with any private insurance and 75% relative to those with any form of public insurance. Thus it cannot be said that those without insurance necessarily receive the care they need.

Overall, the results reported in Table 31-5 suggest that there are wide gulfs in medical care costs in the United States by race, ethnicity, and insurance coverage.

Table 31-4 Number and Percent of U.S. Population with Musculoskeletal Conditions and Annualized per Case and Aggregate Costs of the Conditions, in 2007 Dollars

Years	Number	% U.S. Population	Cost per Person	Aggregate Cost (billion \$)

Each value is based on the average of 2005-2007 MEPS data.

From author's analysis of Medical Expenditures Panel Survey, 1996-2007.

Earnings losses associated with musculoskeletal disorders among the working age population, the component of indirect costs calculable in MEPS, are substantial and growing in real terms; Table 31-6 details their magnitude from 1996-1998 through 2005-2007. The number of persons with a work history between ages 18 and 64 increased from just

Table 31-6 Number of U.S. Persons Aged 18 to 64 with a Work History and Annualized Mean and Aggregate Earnings Losses, in 2007 Dollars, by Year

Years	Number with Work History	Earnings Losses	
		Mean	Aggregate (billion \$)
1996-1998	63,840,865	3350	213.9
1997-1999	62,603,143	4142	259.3
1998-2000	61,508,942	4497	276.6
1999-2001	63,182,182	4451	281.2

2004-2006	74,832,482	5128	383.7
2005-2007	76,301,791	4979	379.9

Each row represents the average of 3 years of MEPS data.

From author's analysis of Medical Expenditures Panel Survey (MEPS), 1996-2007.

under 64 million in the first triad of years covered to more than 76 million in the last triad. Concurrently, the per-person earnings losses among working age persons with musculoskeletal conditions increased from \$3350 to \$4979, or by just less than 50% in real terms. As a result of the increase in the prevalence of the at-risk population and the per-person earnings losses among such persons, aggregate earnings losses among persons with musculoskeletal conditions rose from \$213.9 billion in 1996-1998 to \$379.9 billion in 2005-2007, or by more than three quarters. From Table 31-5, it is evident that, of the \$620.9 billion in medical care costs incurred by all persons with musculoskeletal conditions in 2005-2007, about \$358.5 billion occurred among those between ages 18 and 65. Thus among working age persons, earnings losses, estimated to be about \$380 billion, exceed direct medical care costs by more than \$20 billion.

Figure 31-1 summarizes the overall economic impact of musculoskeletal conditions since the first studies of the cost of illness were conducted by Dorothy Rice and colleagues in the early 1960s.^{4,28-31} It should be reiterated that the availability of the MEPS data makes it possible to study all of the costs incurred by individuals with the same dataset, as opposed to the prior studies by Rice and colleagues based on multiple data sources. This renders exact comparisons to

Figure 31-1 Direct, indirect, and total costs of musculoskeletal conditions as a percentage of gross domestic product, United States, select years. (From references 4, 28-31 (pre-1995) and author's analysis of Medical Expenditures Panel Survey (1996 and later).)

the studies conducted by Rice impossible. Nevertheless, one can compare trends in the Rice studies and, subsequently, trends in the studies using MEPS. The vertical line in the figure indicates the disjuncture between the two sets of studies. In the period covered by the Rice studies, that is, from 1963 through 1995, total costs of musculoskeletal conditions rose from well under the equivalent of 1% of GDP to just under 3% of GDP. During this time, the proportion of total costs due to earnings losses varied between 38% and 59% of the total for a year. The variance in this percentage is a function of whether wages or medical care costs were rising faster.

The National Arthritis Data Workgroup¹⁸ has estimated that the change in methods associated with the initiation of the MEPS accounts for about half of the increase relative to the last of the studies conducted by Rice and colleagues, whereas the remainder constitutes a real increase (i.e., an increase not associated with changes in the methods of analysis). During the time since the MEPS analyses began, the total costs of musculoskeletal conditions have risen from the equivalent of 5.6% of GDP to about 7.3% in slightly more than a decade, or by more than 30% in relative terms. Medical care costs among persons of all ages with musculoskeletal conditions have risen from the equivalent of 3.7% of GDP to 4.5%, or by about 22% in relative terms, while the earnings losses, estimated here only for those aged 18 through 64, have increased from the equivalent of 1.9% to 2.8% of GDP, or by about 47% in relative terms.

A recession is said to occur when the economy contracts by 1% of GDP or more for two quarters or more. In the deep recession that began in 2007, GDP fell by about 7%³² on an annualized basis. The economic impact of musculoskeletal diseases can therefore be said to be the equivalent of a severe recession, although to judge by the increases over time, the onset occurs more slowly. However, the impact is permanent, at least until medical care expenditures either result in improved functionality and concomitant reduced earnings losses or, without that impact, are reduced by decreases in the amount of health care used and/or the unit prices of the services used to treat this group of conditions.

OTHER NATIONS

Studies on the economic impact of musculoskeletal conditions have been conducted in Canada,^{33,34} Australia,³⁵ the United Kingdom,³⁶ Sweden,³⁷ and the Netherlands.³⁸ All use methods broadly similar to the studies in the United States conducted by Rice and colleagues.³⁹ The most recent Canadian study,³⁴ using 2000 data but just published, showed that the economic impact of musculoskeletal conditions was approximately \$22.3 billion CDN, or roughly 2.1% of that country's GDP for that year, similar to the most recent of Rice's studies in the United States. In the Canadian study, indirect costs associated with earnings losses were much greater than direct medical care costs for these conditions. The study in the Netherlands is particularly instructive. In that nation, it was found that musculoskeletal conditions ranked second among all major diagnostic groups in medical costs, exceeding coronary and other circulatory conditions and only being eclipsed by mental retardation.

The demographic structure of the developed nations in which these studies have been conducted are similar, with each facing a pandemic of musculoskeletal disease due to the aging of their populations. Increases are also probably associated with the increased prevalence of obesity in many of the developed nations; obesity is associated with OA. However, we are not aware of systematic studies of the cost of these conditions in the developing world.

COST OF DISCRETE CONDITIONS

The first studies of the cost of illness for discrete rheumatic diseases were conducted about RA and, reflecting the importance of this condition in the practices of rheumatologists and other rheumatology health professionals, the economic impact of RA continues to be the subject of extensive investigation. However, a sizable literature on the economic impact of SLE and OA exists, and there are at least a few studies about the costs associated with ankylosing spondylitis, psoriatic arthritis, gout, and fibromyalgia.

Rheumatoid Arthritis

The costs of RA have been extensively reviewed.⁴⁰⁻⁴⁷ Several studies parse the literature for methodological differences among studies including the perspective of the analysis (individual with the condition, focusing on the share of total costs paid out of pocket; payer, focusing on the share paid by health insurance plans or national health insurance; and society, focusing on all of the resources devoted to health care for the condition, regardless of who pays for those resources, as well as the forgone productivity); type of case being studied (prevalent or incident); and effect of specific treatments including but not limited to the biologic agents.

Among studies of RA not of recent onset and preceding the development of the biologic agents, direct costs in most studies were in the range of \$5000 to 7000 per year, while indirect costs averaged between two and three times direct costs. Within direct costs, approximately two thirds were attributable to hospital admissions even though less than 10% of persons with the condition are admitted to the hospital in any one year. Among those hospitalized, the vast majority were receiving surgical interventions, principally joint replacement surgery.

Among the approximately 90% of persons with RA not admitted to the hospital in a year, costs in the prebiologic era could be quite low. The modal costs for RA in that era were \$685 per year in one study, whereas the median was only \$2715. At the 90th percentile, however, costs were higher than \$8000 per year while at the 95th percentile, costs were in excess of \$30,000.⁴⁸

The high indirect costs of RA are a function of the prevalence of work disability, with rates varying from a low of 34% in one study to a high of 59% in another.⁴⁹ One study reported on the duration of time from onset of the condition until work disability occurred: Of persons with RA, 10% stopped working in the first year after onset, about half had stopped working in the first decade after onset, and 90% left work before the normal age of retirement.⁵⁰

The impact of the biologic agents on costs of RA has been so profound that studies should be divided into those that predate and postdate the availability and diffusion of these agents. In some series, the proportion of persons with RA receiving biologic agents has reached a third or more.⁵¹ At approximately \$20,000 per year per user, medical care expenditures for RA for biologic agents alone now exceed estimates of the total costs of the disease including indirect costs, from the prebiologics era. Several studies quantify the incremental costs associated with the use of the biologics beyond what would be expected for persons with similar health status. Michaud and colleagues⁵² reported that medical care costs for RA were more than \$19,000 per year for persons taking biologic agents, but only about \$6000 for those not, even after accounting for differences in the two populations. Fautrel and colleagues⁵³ reported that the incremental costs associated with etanercept and infliximab were about \$23,000 to \$25,000 per year, or more than three times the annual direct costs of RA in the prebiologics era. Sorensen and Anderson⁵⁴ studied the potential impact of the biologics on the Danish health care service, reporting that under varying scenarios the biologics would raise the cost of treating RA from 50% to 500%. In a study of elderly

persons with RA, Weycker and colleagues⁵⁵ noted that RA care averaged between \$12,000 and \$23,000 in the biologics era, or more than twice the average from the prebiologics era.

However, perhaps the best way to gauge the impact of the biologic agents on the costs of RA is merely to note that, in this disease with a prevalence of less than 1% of the population, pharmaceutical companies find it profitable to advertise the agents on *national* television shows in the United States. Assuming that the prevalence was 0.5% of the approximately 250 million adults in the United States, or 1.25 million, that about a quarter of these used the biologic agents, and that the agents cost \$20,000 per year, then biologic agents would account for more than \$6 billion a year in health care expenditures for RA.

The costs of RA may be substantial early after onset. Merkesdal and colleagues⁵⁶ observed annual indirect costs due to lost wages within the first 3 years of disease. Of note, however, they observed that short-term sick leave costs were higher in the first year than the next two, but that permanent work disability costs increased to partially offset the decrease in sick leave. Similarly, Hallert and colleagues⁵⁷ reported that direct costs in the first year after diagnosis averaged almost \$5000, whereas indirect costs were more than twice as great. Among persons with seropositive RA of about 6 months' duration, Newhall-Perry and colleagues⁵⁸ reported that direct and indirect costs were about \$200 and \$300 per month, respectively. The relatively high indirect costs were a result of the high rate of work cessation (>10% among those employed at diagnosis) and sick leave (>5% in the same group).

The high medical care costs associated with RA, manifest even among those of recent onset, present a paradox for choice of therapy at the level of the individual patient-provider dyad and at the level of the payer and society. On the one hand, there is ample opportunity to reduce much of the nonmedication cost of treatment for joint replacement surgery and for indirect costs due to lost wages by timely use of the newly discovered and highly efficacious biologic agents. On the other hand, iron clad evidence that they can reduce the frequency of joint replacement and work loss is lacking information necessary to prove cost-effectiveness, in part because of methodological problems in the studies conducted including lack of head-to-head trials and uncertainty about the results of the studies that have been done.⁵⁹ Thus we know that the costs of RA are high and growing due to the use of biologic agents, but we do not know whether using them can reduce the indirect costs and the functional losses that lead to joint replacement surgery.

Although the bulk of the now vast literature on the economic impact of RA derives from clinical samples, it is possible to make an estimate for the United States as a whole using MEPS data, with the caveat that there may be individual respondents to the MEPS surveys who are unaware of the specific form of arthritis they have even though a physician would diagnosis them as having RA and, on the other hand, some who inaccurately state that they have RA when that is not the case. The advantage is that MEPS samples from the community at large, eliminating the bias from sampling in tertiary care centers or select health plans. The MEPS estimates were made by merging

five annual waves of data, from 2000-2004. On average in the United States as a whole, direct costs among persons with RA averaged just under \$10,000 a year, whereas earnings losses among those aged 18 to 64 totaled about \$14,000 a year. In aggregate, direct costs and earnings losses associated with RA averaged \$29.1 billion in the years of the analysis, or about 0.3% of the nation's average annual GDP in those years.

Systemic Lupus Erythematosus

The first studies of the costs of RA appeared in the mid-1970s; the first studies of the costs of SLE did not appear until almost 2 decades later. Nevertheless, there is now a substantial literature spanning three continents⁶⁰⁻⁶² and going beyond studies of undifferentiated SLE to focus on the impact of specific levels of disease activity^{62,63} and specific organ manifestations^{62,64-68} on direct and indirect costs. As we have seen, the costs of RA have been historically driven by work disability and joint replacement, but more recently expenditures for biologic agents have come to play an important role. SLE is also associated with high rates of work loss, and certain manifestations, particularly renal failure and neuropsychiatric impairment, result in high medical care costs due to hospitalization. However, the use of biologic agents in SLE is only now a prospect, so biologic agents are not yet a factor in the costs of SLE. The work loss costs may be profound in SLE both because a high proportion of persons with this condition experience temporary or permanent reduction of employment but also because the age of onset is, on average, a decade earlier than in RA.⁶⁹

Comparing the direct costs of SLE to those of RA in the prebiologics era for the latter condition, the magnitude of the direct costs are slightly higher in the former condition, but the distribution is not as heavily tilted to the inpatient environment. In the studies, medical care costs averaged about \$7000 per year, with a range from slightly more than \$4000 to just under \$14,000. On average, the hospital accounted for considerably less than half of direct costs, despite high inpatient costs for the small proportion with admissions, whereas medications accounted for about a quarter. Costs of ambulatory care were of about the same magnitude as medications.

In an important study, Clarke and colleagues compared costs in the United States, United Kingdom, and Canada.⁶⁰ To ensure that prices for services did not affect their estimates, they used the same unit prices for each country. They observed that costs of SLE in Canada and the United Kingdom were of similar magnitude, but both were about 10% to 15% less than in the United States. This extra level of expenditure does not, however, result in better outcomes. Indirect costs are measured using a greater heterogeneity of methods than for direct costs, but for those using similar methods, indirect costs exceed direct costs by an average of about 2:1.⁷⁰ Indirect costs are high in SLE due to high rates of work loss; prevalence of work loss among those employed at onset of disease is estimated to be 15% within the first 5 years of diagnosis and 63% within the first 2 decades.⁷¹ Even though these rates of work loss are certainly worthy of concern in their own right, the labor market outcomes of persons with SLE may be worse than that of persons with

some other diseases of lesser severity because symptoms such as fatigue, pain, and neurocognitive deficits may not be as obvious to the untutored eye.⁶⁹

In studies of the impacts of specific levels of disease activity and specific organ manifestations on direct and indirect costs, there is mounting evidence of the profound effect of lupus nephritis; other measures of renal damage; neuropsychiatric manifestations including memory impairment; and global measures of disease activity and severity and disease flare on costs. For example, in one study, Zhu and colleagues⁶¹ observed that SLE patients experiencing flares incurred twice the total costs of SLE as those without flares, with those experiencing renal or neuropsychiatric flares having the highest levels of costs. Effective treatment to prevent damage accrual to specific organs or to reduce the frequency and severity of flares may result in a substantial reduction in the costs of SLE.

Osteoarthritis

Relatively few studies of the costs of OA have been completed. In part, this is because relatively few formal diagnoses are made of this condition relative to its "true" prevalence because treatment modalities would not change if a diagnosis were made. As a result, many of the costs of OA are subsumed within the broad groupings of "arthritis" and "musculoskeletal conditions." In addition, much of the costs of OA when they are enumerated are due to the side effects of nonsteroidal anti-inflammatory drugs (NSAIDs) including ulcers, or total joint replacement surgery. Another high-cost item has been due to the use of drugs said to decrease the prevalence of NSAID gastropathy, either gastroprotective drugs in concert with traditional NSAIDs or selective COX2 inhibitors that can lower the frequency of gastropathy.⁷²

In the studies that have been conducted from clinical samples,⁷³⁻⁷⁵ average direct costs of OA have been in the range of \$4000 to \$6000 per year, with indirect costs considerably less than that, principally because many persons with OA are no longer in the normal ages of labor force participation.⁷⁶ However, when hospitalization occurs for the complications of NSAIDs or surgery, average direct costs rise severalfold.

These may be underestimates. In a study using MEPS data, direct costs among persons with OA averaged about \$10,000 and earnings losses among persons aged 18 through 64 were of about the same magnitude. Aggregate direct costs totaled just under \$23 billion, whereas indirect costs were of about the same magnitude, \$22 billion.¹⁹

Even these may underestimate the economic impact of OA. In 2004 it was estimated that in excess of 1 million joint replacement surgeries occurred, with the number projected to increase with the aging of the population on the one hand and increasing willingness to operate on younger individuals on the other hand.⁷⁷ Of these surgeries, 83% of hip replacements and 97% of knee replacements were done for OA. These operations alone cost in excess of \$29 billion, about 25% greater than the estimates from MEPS including all other direct-cost items.

Another way to estimate the costs associated with OA in MEPS would be to subtract the costs of RA from the total enumerated in the overarching category "Arthritis" because

most persons in that category do have OA. If one were to do that, the direct costs of OA would total almost \$270 billion, whereas the earnings losses among persons aged 18 through 64 would total about \$28 billion. Together, the economic burden of OA including medical care expenditures and earnings losses among those aged 18 through 64 would be in the range of 3% of GDP.

Back Conditions

MEPS data are ideal for estimating the economic burden associated with back problems because the overarching category does not require a specific diagnosis from a physician but, instead, can be reported by an individual experiencing a back problem. Using MEPS, the author estimated that the prevalence of self-reported back problems increased by about 19% between 1996-1998 and 2002-2004, from 27.4 to 32.9 million; the fraction of the population with such a problem increased by 12% during this time, to 11.3%.

Direct costs per case associated with back problems increased by about 25% over the period covered, from \$4756 to \$5923 in 2004 terms. This increase was largely fueled by an 88% increase in the real value of prescription medicines used for back problems. Overall, direct costs for back problems increased from the equivalent of 1.2% to 1.7% of GDP between 1996-1998 and 2002-2004 as a result of the increase in the direct costs per case and the increase in prevalence. Earnings losses among persons aged 18 to 64 with back problems are relatively slight, averaging \$1871 among the 24.3 million individuals these ages with such problems, or the equivalent of 0.4% of GDP in 2004 terms. Earnings losses are relatively slight because a majority of persons with back problems experience temporary disability rather than permanent work loss, although it should be noted that back problems are common causes of work loss but that such loss occurs with relative infrequency when compared with the high overall prevalence of back problems in the population.

Other Conditions

Ankylosing Spondylitis

Boonen and colleagues⁷⁸ have spearheaded efforts to characterize the burden associated with ankylosing spondylitis in a systematic review of the cost-of-illness studies in this condition and by an article describing the frequency with which various kinds of impact for the condition are experienced.⁷⁹ In the former publication, they note that the total costs associated with ankylosing spondylitis including direct costs ranged between \$7243 and \$11,840, amounts comparable with the cost of RA in the prebiologic era. Woolf⁸⁰ observed that the typical individual incurs relatively high costs for assistive devices and personnel and sustains substantial earnings losses. However, the distribution among cost categories differs among countries. In the United States, coverage for physical therapy is relatively poor and hospital admissions are rarely reimbursed for ankylosing spondylitis, so a larger proportion of total costs of the condition are attributable to wage losses than in other nations.

Fibromyalgia

Annemans and colleagues⁸¹ recently summarized the literature on the economic impacts of fibromyalgia. Fibromyalgia, a controversial diagnostic entity, is defined by persistent, widespread pain and, perhaps, heightened reactivity to painful stimuli compared with those without the condition. Symptoms related to the condition include sleep disturbance and depressive mood. Fibromyalgia disproportionately affects women, many of whom are not employed for pay outside the home and others of whom, if employed, are subject to the normal discrimination in employment that women experience more generally. As a result, direct medical care costs, averaging between \$5000 and \$6000 in the studies reviewed by Annemans and colleagues, dwarf indirect costs due to earnings losses, which averaged between \$2000 and \$3000. This occurs despite evidence that a relatively high proportion of those who are employed at onset either stop working, reduce their hours, or at the least may be subject to temporary disability. Others may change job tasks or switch jobs to accommodate the symptoms. Of note, the studies reviewed show that direct costs associated with fibromyalgia often spike before diagnosis because testing that is part of diagnosis accounts for a substantial burden on society but then may be somewhat reduced as the diagnostic phase of care passes and/or the person with fibromyalgia accommodates to the condition or responds to the combination of pain medications and antidepressives that are often prescribed.

SUMMARY AND CONCLUSIONS

Researchers use cost-of-illness studies to describe the impact of conditions on individuals and society (the positive function) and assist policymakers in allocating resources to redress those burdens (the normative function). Some have criticized the development of such measures of impact because it deflects attention from assigning relative values to interventions that might alleviate the impacts (i.e., from calculating the cost-effectiveness of interventions regardless of the condition for which they are to be used).⁸² In essence they argue that the fact of presenting large estimates of burden may mean that resources may be diverted from using highly cost-effective interventions on conditions of small prevalence even when no effective interventions exist for the conditions of high prevalence and impact, in effect wasting money.

However, an effective counterargument is that allocation decisions will still be made on criteria other than cost-effectiveness. For example, Verbrugge⁸³ long ago noted that fatal conditions tend to garner more attention from policymakers and this puts groups that have conditions with apparent low fatality rates but which are severely disabling at a disadvantage. She observed that men tend to have higher rates of many fatal conditions, particularly cardiovascular disease, whereas women have higher rates of musculoskeletal and neurologic conditions that may have severe impacts but which are not commonly considered to cause mortality.

Certainly societies should allocate services on the basis of the return from the investment, but we must also be certain that we do not unduly discriminate against those

with conditions that do not always garner attention proportional to their effect on people's lives. At the least, we must acknowledge the positive aspect of cost-of-illness studies in describing how resources that are diverted by disease could be used for other purposes were the disease to be eradicated, to provide a measure of the potential returns from effective interventions as they arise.

This debate about the role of cost-of-illness studies notwithstanding, there is no debating that musculoskeletal conditions do divert substantial resources from other uses and the amount so diverted has been increasing due to the aging of the population and increases in the amount spent to treat them, especially for medications. Since the U.S. government began collecting MEPS data slightly more than a decade ago, the gross economic impact of musculoskeletal conditions has grown by the equivalent of 1.7% of GDP, to 7.3%. If one accounts only for the increment expected of persons of similar age and gender, the impact is smaller, but at about a third of that total, not small. Musculoskeletal conditions do divert significant economic resources away from other uses due to the substantial expenditures for medical care and by depriving the economy of the productivity at work and in other activities of those affected by the conditions.

Clinical Trial Design and Analysis

ROBERT B.M. LANDEWÉ •
DÉSIRÉE M.F.M. VAN DER HEIJDE

KEY POINTS

Clinical trials play an important role in new drug development but also can serve to explore existing drugs or interventions further or refine their use.

Pragmatic trials have a lower level of internal validity (methodologic robustness) compared with explanatory trials but a higher level of external validity (generalizability).

A fundamental choice in the consideration of the design of the study is to decide about a superiority design or a noninferiority design.

An appropriate trial design is of decisive importance to optimize the likelihood that the trial provides results that are interpretable, robust, and applicable. The decisions made during the design phase are a reflection of the continuous balance between internal validity and external validity.

Several disrupting factors, such as missing data, dropouts, and confounding, may jeopardize the interpretation of the trial results. The consumers of trial results (investigators, pharmaceutical industry workers, readers of medical journals) should be challenged to interpret the results of a trial in the light of these potentially disturbing factors.

Clinical trials are studies designed to assess the efficacy and toxicity of drugs or other interventions. Although the term *clinical trial* often refers to “randomized clinical trial (RCT),” every study in which patients are exposed to an intervention and in which data are systematically collected can be considered as a clinical trial. Clinical trials play an important role in new drug development, but can also serve to further explore existing drugs or interventions or to refine their use, as in determination of predictive factors for treatment efficacy, or to test treatment strategies. This chapter broadly confines itself to RCTs. It discusses methodologic principles of clinical trials, as well as RCT analysis, in the context of rheumatology, and it unveils limitations of RCTs while briefly discussing alternative solutions in design and analysis. This chapter is intended as an introduction for clinicians and researchers working in the field of rheumatology.

TRIAL DESIGN

Randomized Clinical Trials

The classical template of an RCT includes two (or more) trial arms comparing the drug or intervention of interest (e.g., the new drug) with a control intervention. The latter

may include a placebo or sham intervention, or an intervention that is considered to represent standard care. By definition, the treatment arms are created through the process of randomization, which is pivotal and will be outlined later in greater detail.

To better understand differences in trial design, it is often helpful to distinguish *explanatory* RCTs and *pragmatic* RCTs.¹⁻³ Trials of new drugs, such as those designed for drug registration, aimed at showing efficacy and short-term safety, belong to the group of explanatory RCTs. In general, all elements of trial design, such as selection of patients, sample size, choice of the comparative intervention, and duration of the trial, are chosen in such a manner that the trial can optimally demonstrate a treatment effect, that is, a difference in efficacy between the new drug and the control intervention. The methodologic robustness of a trial, which is dependent on these elements of trial design, is referred to as *internal validity*. Explanatory trials do not always resemble clinical practice. As an example, they often include for methodologic reasons patients with a high level of disease activity who form only a minority in clinical practice. The extent to which clinical trial results can be extrapolated to the common clinical practice is referred to as *external validity*. As a rule of thumb, explanatory trials have a high level of internal validity, which may, however, jeopardize external validity to some extent. Pragmatic trials more closely resemble the clinical situation. Such trials aim to optimize treatment by further exploring existing drugs or treatment strategies. Pragmatic trials incorporate fundamental principles of RCTs, such as randomization, but include a more realistic representation of patients, may have a longer duration, and may allow co-interventions. In general, pragmatic trials have a lower level of internal validity as compared with explanatory trials, but a higher level of external validity. Often, explanatory trials are initiated and sponsored by pharmaceutical industry, but most pragmatic trials are (academic) investigator-driven initiatives.

Randomization

Randomization, the process by which patients are assigned to treatment by chance, is the most important methodologic characteristic of an RCT and deserves some explanation. Randomization makes treatment arms similar for all variables except treatment, or, in other words, randomization divides all known and unknown variables that may or may not be of prognostic importance equally across treatment groups, thus reducing the probability that factors other than treatment may influence the results. It is important to realize that randomization does not completely

preclude imbalances. Differences in variables that are of prognostic importance may simply occur by chance. However, randomization precludes intentional imbalances (e.g., dissimilarities created by physicians who consider a particular treatment more appropriate for a particular patient [selection]).

From a statistical perspective, chance differences will occur more frequently in small study samples than in larger ones, and may be of higher magnitude in small trials. It is therefore necessary to compare treatment groups at baseline with respect to important prognostic variables, and to adjust for differences in the statistical analysis in case of doubt. Usually, computer-generated randomization lists are used to randomize patients in an RCT. Technically, randomization is often performed in “blocks,” so that in every block of four or 10, there will be equal numbers of patients in the treatment and control groups. Randomizing in blocks ensures that if the sample size is less than expected, an equal proportion of patients will be included in each treatment group. Often, in multicenter trials, one center is assigned one or more blocks, ensuring that the numbers of patients receiving the new drug and the control drug are evenly distributed per center.

Some trials randomly enroll patients in strata (stratification) of equal or unequal size. Stratification (a better wording is *stratified randomization*) makes sense only if the variable subject to stratification represents a prognostically important feature. An appropriate example is a situation in which circumstantial evidence suggests that the efficacy of a treatment is different in males as compared with females. Stratified randomization with “males” and “females” as strata implies that randomization to treatment groups occurs after assignment of the appropriate stratum. This allows a justifiable comparison between treatment groups within each stratum because there is prognostic similarity at baseline. Appropriate stratified randomization requires a trial design and a sample size that indeed allows such a comparison (see later discussion on statistical power).

Stratified randomization should be distinguished from post hoc subgroup analysis, in which the “strata” are determined during analysis of the trial. In such post hoc comparisons, prognostic similarity cannot be assured, and statistical adjustments can account for this only rarely.

Design Considerations

A fundamental choice in consideration of the design of the study is the decision about a superiority design or a non-superiority design. The latter theoretically can be further categorized as a noninferiority design and an equivalence design. The basis supporting this choice is the null hypothesis underlying the study. Consequences of the choice of design are important. If a new treatment is tested against placebo, the *a priori* hypothesis is that this new drug is more effective than placebo, and a superiority design is a rational choice. If for a particular disease or condition, treatments are already available, it is ethically often not justifiable to subject patients to a placebo treatment for longer periods. It is not always rational to assume that a new treatment will be better than the best available treatment at that moment, and a superiority design would have a high likelihood of failure. In such situations, one can opt for a nonsuperiority

design. These designs have the underlying hypothesis that the treatment to test is at least not worse than (or, equivalent to) the comparative treatment, which can be the *standard of care*, or alternatively, the best currently available treatment.

In a *superiority design*, the question is whether the new treatment is more efficacious than the control intervention (e.g., placebo). Formally, such a study tests whether the null hypothesis of *no difference between both treatment groups* can be rejected. To do so, investigators agree on a *minimally clinically important difference* (MCID) between the intervention of interest and the control intervention such that a study should be able to demonstrate, and they design the study in such a way that this difference can be demonstrated with high likelihood (statistical power) when it really exists (see later). In a *noninferiority design*, the reasoning is opposite. The null hypothesis is that the new treatment is less efficacious than the control intervention.^{4,5} Even if the new intervention and the control intervention are truly similarly effective, a trial will almost never yield a result with a treatment effect of exactly zero (no difference). There will be variation around zero, and it is the task of investigators to decide in the design phase of the study which deviation from a treatment effect of zero they will accept to conclude that the interventions are equivalent, the *noninferiority margin*. Determination of the MCID in a superiority design and the noninferiority margin in a noninferiority design is a subjective decision with important consequences for the sample size. When it is important in a superiority design to be able to demonstrate very small treatment effects with a high likelihood, large sample sizes are needed; the same is true with a very narrow noninferiority margin in a noninferiority design. Especially with a noninferiority design, considerations other than efficacy alone may give guidance to the level of the noninferiority margin. If a new drug is less toxic or less costly than existing drug(s) on the market, and as such may provide additional benefits, one could be more lenient with regard to determining the noninferiority margin. In general, noninferiority designs require (far) more patients than are required by superiority designs.

Subject Selection

Subjects who are entered into clinical studies should meet accepted criteria for the disease or disorder under study. Most rheumatologic conditions lack single and unequivocal diagnostic tests, and classification criteria have been developed to identify patients with similar characteristics.⁶ These classification criteria serve as eligibility criteria in an RCT. To homogenize patient populations for scientific purposes, classification criteria are designed to be highly specific. As a consequence, sensitivity may fall short, and classification criteria are often of limited use in diagnosis. The high specificity of classification criteria has implications for the makeup of the trial population. In general, patients with classic, often severe disease are overrepresented, and those with early, less typical disease are underrepresented.

In many trials in rheumatology, patients must meet certain criteria for disease activity or duration. Some trials require that the patient experience a flare after withdrawal of medication as evidence of active disease. Other studies define disease activity before withdrawal of medication as

evidence of lack of response to current treatment. Disease severity can be defined by accepted clinical criteria or by lack of response to previous treatments. For example, RA studies may be limited to patients who have not yet received methotrexate (who presumably have relatively early disease or mild disease) or to patients who have failed treatment with at least one other disease-modifying antirheumatic drug (DMARD) (greater disease severity). There are ethical and methodologic reasons for the use of such activity and/or severity criteria. Ethical arguments may proscribe that a novel intervention is first tested in patients with severe, sometimes intractable disease in which common alternatives have failed. Methodologic arguments are that a treatment effect can best be demonstrated in a population of patients prone to change. Most inflammatory rheumatic diseases have a cyclic course characterized by exacerbations and remissions. Patients with a high level of disease activity will tend to improve over time, even without an intervention—a phenomenon known as *regression toward the mean*; the additional effect of a new intervention in comparison with a control treatment can be demonstrated more easily in such a context.

Exclusion criteria usually include conditions such as cancer; cardiac, hepatic, or renal disease; abnormalities in hematologic parameters, medication allergies, and pregnancy. Exclusion criteria serve to decrease background noise or variability due to differences in patient characteristics. In general, inclusion and exclusion criteria will homogenize the trial patient population and contribute to an environment that is most optimal to demonstrate a treatment effect. Inclusion and exclusion criteria also prevent entry of patients in whom an adverse response is more likely to occur and those for whom the experimental treatment could be dangerous a priori. As such, inclusion criteria and exclusion criteria contribute to a high level of internal validity but jeopardize external validity. Explanatory trials usually have a comprehensive set of inclusion and exclusion criteria. Pragmatic trials are more lenient in this regard because they should better reflect the common clinical practice.

Informed Consent

Ethical considerations determine whether eligible subjects participate in a clinical trial. Governmental agencies of most countries require that institutions involved in human research have a local institutional review board (IRB). The IRB reviews all protocols before implementation and monitors ongoing studies at its institution. A crucial element in the review of a trial is the informed consent process.⁷ The consent form should explain to the study participant the purpose of the study, all potential benefits and risks (including risks to pregnant mother and fetus), alternatives to participation, and who is responsible for conducting the study. Patient confidentiality should be ensured. The consent form should clearly state that participation is completely voluntary, and that refusal to participate or withdrawal from the study will not affect future care. If compensation is provided, this must be documented in the consent form. Participants should be given contact information for questions or in case of injury and a statement about whether any medical treatment will be given if injury occurs. Investigators are responsible for ensuring that the

risk to subjects is minimized and appropriate for the anticipated benefits.

Follow-up Considerations

The optimal duration of the trial represents a compromise between economical, ethical, and methodologic considerations. A trial should not be too short because an intervention needs time to exert its potentially advantageous (but also deleterious) effects; in particular, a short trial does not reflect the clinical reality of most rheumatologic conditions. Equally, a trial should not be too long because RCTs are expensive, patients should not be subjected to experimental interventions with uncertain adverse events for an excessive time period, and too much *longitudinal bias* should be avoided. Longitudinal bias may occur if during the trial, the treatment groups increasingly become dissimilar as the result of selective dropout, co-interventions, or other patients' or physicians' behavior. Selective dropout may occur if patients with a particular profile preferably withdraw from one of the treatment groups, thus creating prognostic imbalance. A common example is that of an RA trial comparing an effective drug versus placebo. Patients with relatively severe and active disease in the placebo group may preferably discontinue trial medication and may drop out because they do not experience benefit, while less severe and less active patients remain in the trial. Co-interventions—allowed or not allowed—may similarly jeopardize prognostic similarity if they occur in an unbalanced (i.e., unequal) manner across treatment groups. A common example is a trial that tests a nonsteroidal anti-inflammatory drug (NSAID) versus placebo with respect to the relief of pain. Simple analgesics, which are preferentially used in the placebo group, may inadvertently influence pain scores, leading to incorrect conclusions. The treating physician may contribute to prognostic imbalance by prescribing co-interventions, or in general terms by treating patients differently according to their clinical response or the occurrence of adverse events. A relatively short follow-up will decrease the likelihood that unintended events will occur and as such contributes to maintaining prognostic similarity and increasing internal validity.

Explanatory trials usually have a follow-up duration that is as short as possible, and co-interventions are prohibited. The most important limitation of short-term trials in life-long rheumatologic diseases is that they do not appropriately reflect the course of the disease encountered in clinical practice. Sometimes, RCTs, especially pragmatic trials, have a long trial duration that better reflects the clinical reality. In such a trial, internal validity is deliberately sacrificed to some extent in favor of external validity (generalizability) and the yield of long-term information.

Blinding

In double-blind studies, neither the patient nor the investigator is aware of the treatment group assignment. In single-blind studies, the investigator is aware of the treatment allocation, but the patient is not. In open-label studies, both patient and investigator are aware of the treatment assignment. The most important reason to blind treatment allocation is to avoid that any expectation about the type

of treatment provided could influence the measured outcome (expectation bias), especially (but not exclusively) if the measured outcome includes subjective components. Note that *subjective* refers to the patient (e.g., pain scores) as well as to the investigator (e.g., joint scores). To avoid the latter, many drug trials make use of independent (joint) assessors, who are not responsible for decisions regarding patient care and are blind for the treatment. Another common example of a blinded independent assessor in rheumatology is the reader of radiographs in imaging studies in RA, psoriatic arthritis, or ankylosing spondylitis (AS).

Regardless of any precaution taken, unblinding may inadvertently occur because of identifiable adverse reactions or minor side effects, lack of efficacy, or changes in laboratory parameters. A meaningful effect of such a type of unblinding is not easy to prove, nor can it be adjusted for in the analysis.

Choice of Outcome Variables

Any clinical trial has one or more outcome variables of interest. *Outcome* is broadly defined and refers to a clinical situation or a change in a clinical situation that is quantifiable by using assessment instruments. Outcome variables can measure *real outcome* that directly affects the patient (e.g., vertebral fracture in osteoporosis), or alternatively can reflect a situation that is associated with real outcome but does not (yet) affect the patient (e.g., low bone mineral density in osteoporosis). The latter type of outcome is often referred to as *surrogate outcome*. Reasons to use surrogate outcome measures rather than real outcome measures are that the former occur (far) earlier and more frequently and can often be assessed on a continuous scale (which is a statistical advantage), and the latter often describe an event (the presence or absence of a clinical situation) with negative implications for statistical power.

The Outcome and Measurement in Rheumatology Clinical Trials (OMERACT) initiative was created to bring unanimity to the multitude of outcome measures in rheumatology on the basis of expert consensus.⁸ Its activities were initiated in RA and were expanded to include most other rheumatologic diseases. The OMERACT framework is the so-called OMERACT filter, which describes the methodologic prerequisites that an appropriate outcome measure should fulfill to be considered valid for clinical trials. The OMERACT filter prescribes three validation requirements: An outcome measure should be truthful, discriminatory, and feasible.

Truthful refers to whether an outcome measure truly measures what it is intended to measure, and approximates the concepts of face, content, and construct validity. It means, for example, that the disease activity score (DAS) in RA should truly measure what is considered important in RA (swelling and tenderness of joints) (*content validity*) and is a relevant construct to describe the process of RA, for example, because the disease activity score is associated with radiographic progression and limited physical function (*construct validity*). *Discriminatory* refers to whether an outcome measure can reliably be measured (intraobserver variation and interobserver variation), whether it can distinguish between two stages of the disease (e.g., RA with high disease activity vs. RA with low disease activity),

whether it should be applied to groups of patients or to an individual patient, whether the measure is sensitive to change (e.g., whether the DAS measurably decreases if the disease improves), and whether the measure can discriminate between groups of patients on effective therapy versus those on placebo or less effective therapy. *Feasible* refers to whether an outcome measure is easily applicable and cheap in the setting in which it is intended to be used.

Ten biannual OMERACT conferences have resulted in sets of outcome measures for almost all inflammatory rheumatologic diseases and for numerous noninflammatory disorders. These so-called core-sets have importantly improved homogeneity across different clinical trials, thus favoring comparability. In the design phase of a clinical trial, it is highly recommended to choose a primary outcome measure from these core-sets, and to measure all components of the core-set as secondary outcome measures. Reporting of all core-set measures prevents selective reporting of only positive results with respect to a few variables.

Increasingly, indices are replacing single-outcome variables in rheumatology. An *index* is a weighted or unweighted combination of single variables that together reflect a particular domain of outcome.⁹ A general rule is that indices perform better than single-item variables only if they consist of variables that correlate moderately with each other. If variables correlate at a too high level, there is redundancy of information. If variables do not correlate, they will reflect different domains; this complicates interpretability, and it is better to separately describe them. Important examples of useful indices in rheumatology are the already mentioned disease activity score (DAS),¹⁰ the ankylosing spondylitis disease activity score (ASDAS),¹¹ and the American College of Rheumatology (ACR) response criteria in RA.¹²

Measuring Effect

After the outcome measures are chosen, it is important to consider how the change in outcome measures is measured in the clinical trial. One could simply calculate a before-after difference in a continuous variable (a change score), but this is statistically not necessarily the best approach. The ACR has developed the ACR20 response criteria as a tool to determine in clinical trials whether one drug is more efficacious than another or placebo.¹² The ACR20 is an index that contains several outcome measures from the World Health Organization/International League against Rheumatism (WHO/ILAR) core-set for RA,¹³ which is based on expert consensus about different measures used to assess disease activity. The ACR20 response criteria require a 20% improvement and have been thoroughly validated in several validation steps, have been shown to perform better in trials than individual core-set measures, and currently are the standard for measuring drug efficacy in clinical trials. ACR50 and ACR70 response criteria have been derived from ACR20 response criteria in that they require a higher level of improvement. These derivatives have never been appropriately validated but have proved very useful in drug research, despite an inferior discriminatory potential in comparison with ACR20 response criteria.¹⁴ A specific limitation of the ACR70 is that the baseline disease activity needs to occur at a certain (high) level to actually allow a 70% improvement.

The European League against Rheumatism (EULAR) has endorsed its own response criteria in RA, which are based on the DAS.¹⁵ The DAS is a continuous index measure that includes four core-set measures in a statistically weighted manner. The advantage of the DAS, which also underwent numerous validation steps, is that it describes a state of disease activity rather than a response, or a change. The EULAR response criteria consist of categorical response criteria (good response, moderate response, and no response) that are based entirely on the DAS and require an absolute change in the DAS, as well as a certain state level of the DAS.¹⁵

Another disease in which response criteria have been developed for use in clinical trials is ankylosing spondylitis (AS). The ASsessment in AS (ASAS) International Working Group has developed the ASAS20 response criteria, which include four patient-oriented disease activity measures for use in clinical trials with AS.¹⁶ ASAS has also defined cutoff values for continuous change over time in the previously mentioned ASDAS, reflecting clinically important improvements that can be used as outcome measures in clinical trials.¹⁷

In general, the consensus-based response criteria have contributed to better trial design, better trial conduct, and better comparability across trials. An important drawback still is that interpretability of the different indices ("What does it mean that a patient has experienced an ACR20 response?") remains difficult.

Sample Size and Statistical Power

Statistical power is the likelihood that if a treatment effect truly exists (or drug A is truly better than drug B), the trial will indeed demonstrate this with statistical significance. So a power of 0.80 (80%) means that if there is a true difference between the treatment group and the control group, the likelihood that this RCT will indeed confirm that difference is 80%. At the basis of this definition is the reasoning that *truth* (difference or not) is not known, that we never will know the truth with absolute certainty, and that we can only approximate the truth by performing RCTs. Intuitively, an RCT will not always give the right answer. An RCT may conclude that there is a difference, while in truth there is not. Or alternatively, a true difference will not be supported by the results of the trial. The former is termed a *type I error*, and the latter is a *type II error* (Figure 32-1). The theoretical problem is that by definition, we do not know which RCT gives the right answer and which does not. Although we do not know the true answer, we try to design the trial in such a manner that type I errors and type II errors are minimal. The likelihood of type I and type II error is less with larger sample sizes. As a consequence, the likelihood of correctly drawing a conclusion from the experiment of one RCT is increased by increasing sample size. Apart from sample size, the likelihood that a study can detect a difference between treatment groups also depends on effect size (i.e., if the treatment has a larger effect, it is easier to detect with smaller sample sizes) and reliability of the outcome measure (if the outcome measure is more precise, or is less influenced by measurement error, it is easier to detect with smaller sample size).

	Truth	
	Drug A is better than drug B	Drug A is not better than drug B
Trial result	True-positive trial result ↓ Correct rejection of null-hypothesis	False-positive trial result (Type I error) ↓ Erroneous rejection of null-hypothesis
	False-negative trial result (Type II error) ↓ Erroneous acceptance of null-hypothesis	True-negative trial result ↓ Correct acceptance of null-hypothesis
	Drug A is better than drug B	Drug A is not better than drug B

Figure 32-1 Interpretation of the trial result in the context of the unknown truth of a trial challenging the null hypothesis that drug A is not better than drug B.

The probability of a type I error (false-positive result) is referred to as *alpha*, and is better known as the level of statistical significance. The probability of a type II error (false-negative result) is *beta*. Statistical power is defined as (1 minus beta). If beta is 10%, there is a 90% likelihood of finding a difference between groups of the expected magnitude or greater when this difference truly exists. Usually, alpha, or the *p* value, is set at 0.05, and beta is set between 0.2 and 0.1 (power of 80% to 90%). An ethical consideration is that type I error should be avoided because it may directly and negatively affect patient care (a new drug is falsely considered to be better than an existing drug). Type II error is subtler but should be avoided for more than one reason. First, new and effective treatments may not reach the market for false reasons, but more important, trials with a high probability of type II error are truly inconclusive. Because new drugs may cause harm, a trial that a priori does not allow a firm scientific conclusion is ethically unjustifiable and costs a lot of money with no yield.

Sample size is one of the most important determinants of the power of a study to find a treatment difference. To determine the appropriate sample size for a study, the investigator needs to make an estimation of the effect size of the intervention (i.e., the difference in outcome between treatment groups, the minimum clinically important difference [MCID]), the variability of the data (e.g., standard deviation), the statistical test to be used, and the alpha (*p* value) and beta (i.e., false-negative rate) levels. It is important to consider nonspecific effects (placebo effect, regression toward the means) (e.g., the proportion of subjects who meet criteria for improvement in the placebo group), which have been reported as high as 20% to 40% in studies of patients with RA. The variability or standard deviation of the outcome measure can be estimated from pilot data or from other published clinical trials.

Often the sample size in each treatment arm is the same, but unequal but proportional treatment groups can also be used (2:1 ratio of treated subjects to controls). RCTs with equal-size treatment groups have greater statistical power, but unequal groups are sometimes used to maximize the number of patients who receive treatment, especially if information on safety is the most important reason for the

trial; patients sometimes are more willing to enter a trial in which they have a greater likelihood of receiving an active treatment.

Declaration of Helsinki

The Declaration of Helsinki of the World Medical Association (WMA) (1964) is a document that spells out a set of ethical guidelines for physicians and other participants in medical research.¹⁸ It is considered the most widely recognized source of ethical guidance for biomedical research. The fifth revision (Edinburgh, October 2000)¹⁹ contains 32 paragraphs that aim to find a balance between the physician's duty to *promote and safeguard the health of the people* (paragraph 2), implying that *the well-being of the human subject should take preference over the interests of science and society* (paragraph 5), and the scientific and societal appreciation that *medical progress is based on research which ultimately must rest in part on experimentation involving human subjects* (paragraph 4), inevitably involving *risks and burden* (paragraph 7). The Declaration is not a static document, and current debate focuses on *the place of placebo-controlled trials* (paragraph 29).²⁰ Whereas this paragraph, which raised a lot of argument, justifies placebo-controlled trials only in those circumstances in which *no proven prophylactic, diagnostic, or therapeutic method exists*, a Note of Clarification by the WMA outlines a somewhat more liberal interpretation of this paragraph, providing circumstances in which placebo-controlled trials are allowed, even if proven therapy is available.

It is generally accepted and required by governmental institutions and institutional review boards that trial design, trial conduct, and trial report are in accordance with the stipulations of the Declaration of Helsinki.

Place of Noninferiority Designs in Rheumatology

Paragraph 29 of The Declaration, issuing the place of placebo-controlled trials, has raised interest in designing noninferiority trials in rheumatology. The recently developed biologic therapies have had a very important impact on the treatment of chronic inflammatory diseases. If paragraph 29 of the Declaration of Helsinki is interpreted conservatively, this means that placebo-controlled trials ethically are not justifiable anymore in RA, AS, and psoriatic arthritis. It immediately follows from paragraph 30 of The Declaration (*every patient entering into the study should be assured of access to the best proven therapeutic methods identified by the study*) that future trials investigating new treatments in these diseases should include the best available treatments in the control arm. The introduction of these ethical principles will have methodologic consequences because RCTs with a superiority design become virtually impossible as a result of the high level of efficacy in the control group.

The only acceptable alternative is the noninferiority trial, which was briefly discussed previously. An illustrative example of a noninferiority design, emerging from the controversy about the cardiovascular safety of NSAIDs and cyclooxygenase-2 (COX-2) inhibitors, is the Multinational Etoricoxib and Diclofenac Arthritis Long-term (MEDAL)

study program,²¹ which we will briefly discuss here. Although this program targeted cardiovascular safety rather than efficacy, the noninferiority principles underlying the study are applicable in different settings. The primary hypothesis of the MEDAL study was that treatment with etoricoxib was noninferior to treatment with diclofenac. As a noninferiority margin, a relative risk of 1.30 was chosen. It was defined before the start of the trial that the upper limit of the 95% confidence interval for the hazard ratio (etoricoxib vs. diclofenac) should not exceed the noninferiority margin to justify the conclusion that etoricoxib was noninferior to diclofenac with respect to causing cardiovascular events. This implies that the relative risk itself obviously should be far lower than 1.30 to justify a conclusion of noninferiority. In fact, it was assumed based on previous experience that diclofenac would yield a cardiovascular event rate of 1.3%. With approximately 40,000 patient-years of exposure, it was possible to calculate that the maximum absolute event rate in the etoricoxib group that would still meet the noninferiority criterion would be 1.46% or, in other words, an excess of 1.6 cases per 1000 patient-years of treatment. This example clearly illustrates that noninferiority trials always imply a certain expense (here, a number of excess cardiovascular events). This expense may possibly be limited by narrowing the bound of noninferiority, but this is achieved at the cost of increased sample size in an exponential manner. So, the noninferiority margin is determined as the result of careful considerations about drug safety (that require a margin very close to 1) on the one hand, and the statistical appreciation that demonstration of true equivalence is not possible on the other hand.

Conclusion

An appropriate trial design is of decisive importance to optimize the likelihood that the trial will provide results that are interpretable, robust, and applicable. Usually, decisions made during the design phase are a reflection of the continuous balance between internal validity and external validity. Which of both characteristics prevails in the ultimate design depends on the aims and the context of the trial. The ideal trial design does not exist. It is the challenge of investigators to find the most appropriate design for their goal.

TRIAL ANALYSIS

Hypothesis Testing

Suppose that a scenario with a particular disease for which an effective treatment A exists, and a new treatment B is proposed. It is not known whether the new treatment B will be more effective than the established treatment A, and a clinical trial should give resolution. It is useful to realize that this trial provides only an approximation of the truth that we—by definition—do not know. If you were able to repeat this trial many times, you may find a mean treatment effect across trials that is the best possible approximation of the truth, and most trials provide results that are close to this mean treatment effect. However, a few trials give more deviant results by chance. Because you will not be able to truly carry out this trial numerous times, you will have to

interpret the results of your particular trial in the context of a high number of illusory trials with exactly similar design. To do so, a null hypothesis of the truth should be carefully formulated. The character of the null hypothesis depends on the type of trial. In a classic superiority design, in which, for example, a new drug is tested against an established drug, the null hypothesis of the truth states that the new treatment is *as effective as* the established (control) treatment. In a noninferiority design, however, the null hypothesis of the truth states that the new treatment is *less effective than* the established treatment. Statistical analysis will challenge the actually observed trial results against the null hypothesis of the truth. Essentially, the statistical test provides the probability that a treatment effect (e.g., the difference in proportions of ACR20 responders between treatment groups, or the difference in the mean decrease in DAS) can be found that is as large as what was demonstrated in this trial—or even larger—*while in truth such a difference does not exist*. In the paragraph about statistical power, we have referred to this scenario as type I error, or alpha, and its likelihood is called the *p value*. Usually, we consider a probability of type I error of less than 5% ($p < 0.05$) sufficiently low to safely assume that the null hypothesis of the truth is not a likely hypothesis, and that it can be rejected. We now decide that the new drug is not as effective as the established drug. Note that *not as effective* may imply *better than* as well as *worse than*. Statistical testing does not differentiate between the two scenarios (*two-sided testing*). Crude data should provide the correct interpretation.

The advantage of thinking in probabilistic terms (this trial is only one example of many possible trials with similar design) is that you immediately accept that there is always a chance that, even with very convincing results, the interpretation of this trial may be false. The lower this chance is, the more convincing is the interpretation of trial results. We have also alluded to the scenario that a trial does not show a treatment difference, when in truth there is such a difference: type II error, or beta. Such a trial lacks (statistical) power. Sample size is most often of pivotal importance; a classic example of potential type II error is the small clinical trial with a superiority design that tests a new drug against an established drug. Such a trial may give a treatment effect that is of potential clinical interest, but the *p* value exceeds 0.05 (not statistically significant).

It is important to make a number of reservations clear here. In analogy with type I error, one can never be certain whether type II error is truly responsible for not statistically demonstrating a potentially important difference. One can only suspect type II error as a cause and approximate the probability that it occurs (power calculation). *A priori power calculations* during the design phase inform you about the probability that the designed trial will statistically “help you” (rightfully reject the null hypothesis) if a particular treatment effect is demonstrated. *Post hoc power calculations* can be made after the completion of the trial, using the actually demonstrated treatment effect. Post hoc power calculations inform you about the power of this trial to statistically support the observed difference *if this difference would have been considered clinically important before the trial*. Insufficient post hoc power (e.g., 0.30) is an indication that type II error is operative, but it does not *prove* type II error.

Intention to Treat

A classical clinical trial with a superiority design is analyzed on the basis of *intention to treat (ITT)* by default. ITT means that every patient is analyzed as belonging to the group to which he or she was allocated by randomization, regardless of what happened with this patient afterward. In the extreme scenario, a patient who is randomized to group A may drop out even before the first drug dose is administered, and may be treated outside the clinical trial by his or her physician with the drug that is actually being administered in group B (cross-over of treatment). True ITT requires that this patient, regardless of the data that are present or missing, is analyzed in group A, even if he or she has experienced the effects of the drug in group B. ITT is considered the only means of analysis that preserves the prognostic similarity that was created at baseline. It should be noted here that many trial reports mention an ITT analysis, but that such an analysis often is not rigorously performed. For example, randomized patients who did not receive treatment are often excluded from the analysis.

Alternatively, a trial analysis may be limited to only those patients who completed the study (completers analysis), or to those who completed the study while complying with the study protocol (per-protocol analysis). Both types of analysis may introduce bias; as a consequence, prognostic similarity should not be assumed. Dropout, for example, can occur because of lack of efficacy, and completers may provide a less severe representation of the entire trial population (see later). Often, a completers analysis tends to magnify the treatment effect, and an ITT analysis is more conservative. In a noninferiority trial, however, the situation is just the reverse: The ITT analysis tends to favor noninferiority, and the completers analysis or the per-protocol analysis is more conservative in this regard.

Problem of Incomplete Data

One of the major threats in the interpretation of results of clinical trials is early withdrawal or dropout. Early withdrawal may occur for a variety of reasons. Some patients withdraw consent immediately after randomization, even before the first drug dose is given, because they simply changed their mind. Patients may drop out because of actually occurring or feared adverse events, because of lack of efficacy (no response, disease progression, unrealistic expectations), because of a combination of both, or because they have passed away or have relocated. Usually, dropout results in missing data, in that most patients do not come back for outcome measurement. Often, patients who formally withdraw are encouraged to continue trial assessment, but it is difficult to decide how to handle the data of these patients because they often are treated with different drugs outside the trial. The trial analysis suffers from missing data in several aspects. First, the individual response or disease course cannot be calculated anymore, but leaving out the entire patient data jeopardizes statistical power, especially if the number of withdrawn patients is high (e.g., >20%). Second, it is important to realize that early trial withdrawal is not a random process. It is easy to imagine that the most severely afflicted patients are at risk for efficacy failure; this may lead to selective dropout in a trial with high treatment

contrast, or may cause certain subgroups of patients to be at risk for particular adverse events that occur preferentially in one of the trial arms.

The net result of these inadvertent selection processes may be that treatment groups that were entirely similar at baseline lose their prognostic similarity during the trial. Indicators for selective dropout include differences in rates of dropout between treatment groups, differences in reasons for dropout between treatment groups, a high rate of dropout for a specific reason that is reducible to a specific treatment, and so forth. Usually, missing data are handled in the database by data imputation to keep the patient in the trial analysis. *Data imputation* means that a missing data point is supplied by an imaginary value. Several means of imputation are available, and no consensus has been reached about the best way to impute. Most likely, the best imputation method depends on the characteristics of the outcome measure, such as the natural course of this outcome measure. *Last observation carried forward* (LOCF) imputation is a frequently applied method of imputation in which the last truly measured value is imputed (carried forward) in subsequent (missing) data points. Other imputation rules include imputation of a mean group score of the same or the comparator group, imputation of the 95th percentile, and linear interpolation or extrapolation. More sophisticated multiple imputation techniques impute figures that are considered most likely on the basis of regression analysis of the present data. It is not easy to predict how different imputation rules affect study results. Increasingly, investigators perform sensitivity analyses with different imputation rules to challenge the robustness of their trial results. A trial result that is robust to various means of imputation has more credibility than a trial result that is dependent on the means of missing data imputation.

Presentation of Trial Results

An increasing number of journals require the presentation of trial results in accordance with consensus guidelines (such as the CONSORT guidelines)²² to increase comprehensibility and to maximize information. Such guidelines require exact presentation of the randomization process, a description of blinding, eligibility criteria (about inclusion and exclusion), and many others. An appropriate trial report should include exact information about the fate of all patients after randomization, including the major reasons for withdrawal. It is essential that the total numbers of patients per group can be reconstructed. Increasingly, such information is provided in a flow chart.

The initial part of data analysis involves examining the baseline characteristics of the trial groups, including demographics, previous and current treatments, and disease characteristics (e.g., severity scales, duration, extent of organ involvement) with descriptive statistics. Occasionally, baseline characteristics per group are statistically compared, and baseline similarity is assumed if no statistically significant differences between groups can be shown. Such an approach is rather useless and sometimes is overtly false. Groups are similar by definition because they were formed by randomization. Randomization is a probabilistic procedure, and groups may statistically differ in one or more variables at baseline just by chance. Very often, such differences are

small in relation to the treatment effect, or the particular baseline characteristic is not associated with the measured outcome and therefore is not contributory. On rare occasions, baseline differences are not negligible, and the trial result should be adjusted for these differences by multivariate analysis (e.g., regression analysis, analysis of co-variance). A particular problem may occur in small trials, if even clinically important differences at baseline are not statistically significant, but their impact on the treatment effect may be substantial. A general rule is to “eyeball” baseline differences and to adjust the statistical analysis for those variables that show potentially important differences.

Descriptive Analysis

Simple descriptive analysis includes the presentation of means and standard deviations in cases of normal (parametric) distribution of continuous data (e.g., DAS, ASDAS), or medians and key percentiles in cases of not-normal distribution of continuous data (e.g., Sharp scores). Dichotomous data (e.g., ACR20 responses) are presented as proportions or rates, and ordinal/nominal or categorized data as percentages per category. Graphic representations (e.g., line graphs, bar graphs) are preferred because they give the clearest representation of the treatment effect. An illustrative example of visual presentation of data is the use of probability plots for radiographic data.²³ Emphasis should be on the primary outcome variable, but all measured outcome variables should be presented. It is recommended to present data such that they can be used post hoc for systematic reviews or meta-analyses. This implies that status scores plus a measure of variability (e.g., mean DAS at baseline and at follow-up, standard deviations) and change scores plus a measure of variability (e.g., mean change score, standard deviation of change score) should be presented for primary and secondary outcome variables. Dichotomous outcome variables (e.g., ACR20 response criteria) should be accompanied by extensive information about the status values of (separate) variables. It is relevant to present not only response measures (e.g., ACR20) but also state measures (e.g., absolute DAS) because the combination of the two yields additional information and increases the interpretability of trial results. A useful extension of state measures is the concept of patient-acceptable symptom state (PASS). The PASS reflects that level of symptom severity that best discriminates an acceptable situation from an unacceptable situation from the perspective of the patient.²⁴ PASS levels can be determined by different methodologic methods and are presented as proportions or rates.

Statistical Analysis

Because the process of randomization provides prognostic similarity at baseline, the statistical analysis of a clinical trial is in fact simple, as long as one assumes that prognostic similarity is preserved during the trial. The statistical test of choice is a test for binomial data (e.g., Chi square test) if the outcome measure of choice is dichotomous (e.g., ACR20, ASAS20 response criteria), and a test for continuous data (e.g., Student *t*-test, Mann-Whitney *U* test) if the outcome measure is continuous (e.g., DAS, ASDAS). An extension of the statistical test that provides useful

information to increase interpretability is the 95% confidence interval (95% CI) of the treatment effect. The 95% CI can be calculated for the treatment effect measured by continuous and dichotomous outcome variables. It provides the range within which the estimate of the treatment effect will lie in 95% of cases in the imaginary situation that this trial will be repeated numerous times. If the lower limit of the 95% CI of the mean treatment effect in a trial comparing drug A and drug B does not cross zero, this means that 95 out of 100 times that this trial is repeated, drug A is better than drug B, but 5 times, drug A is not better than drug B. Note that the formulation of the 95% CI closely resembles that of the p value.

Statistical Significance and Clinical Relevance

Clinical trials can be designed in such a way that even very small treatment effects can be statistically demonstrated. Explanatory trials in which new drugs are tested are often performed in a highly selected population of patients with strong adherence to the protocol, without co-morbidity, and with a high probability of responding. Sometimes, sample sizes are huge ("overpowered"). Such trials aim at a high level of internal validity and a low probability of type II error, but it is difficult to immediately interpret the results in the clinical situation, because the mean treatment effect can be so small that it is considered not relevant in the context of clinical practice, and patients in the trial often do not resemble the individual patients in practice (external validity). Guidance is available to evaluate the quality of a clinical trial.²⁵ For example, a trial may demonstrate a small improvement in a primary outcome criterion that is statistically significant, but the effect may not have clinical importance because it is not sufficient to impact quality of life or survival, or it does not outweigh the risk or cost of treatment. A result may be statistically and clinically significant but may have little medical relevance because the benefit does not outweigh the risk or cost of treatment, or because the benefit is seen only in a very small subgroup of patients.

Confounding

Confounding is a special type of bias (systematic error) that can occur in a trial when the trial groups differ with respect to a particular factor other than trial treatment (prognostic dissimilarity). If this factor is also related to the outcome measure of interest, a fake treatment effect may emerge that will erroneously be attributed to the difference in treatment (confounding). As long as confounding factors are known, measurable, and indeed measured, one can adjust for them in the statistical analysis. But if such variables that are referred to as prognostically important are not measured (or even are not known), adjustment is impossible. The likelihood of confounding is far greater in observational studies than in randomized trials, and we will use an example from an observational study to clarify matters. If in an observational cohort study, the efficacy of the DMARD sulfasalazine (SSZ) in the treatment of RA is compared with that of methotrexate (MTX), and it is common practice to give SSZ treatment primarily to less severe patients (e.g., rheumatoid factor [RF]-negative) and MTX to more severe patients (RF-positive), radiographic progression may be less

in patients treated with SSZ than with MTX. It is difficult to determine whether this difference is due to differences in efficacy between SSZ and MTX, or to differences in the severity of RA that may also drive radiographic progression (prognostic dissimilarity). Variables such as RF in this example may confound the relationship between treatment and outcome (radiographic progression). In this example, with a well-known confounder, the analysis may adjust for differences in RF positivity. However in theory, many unknown variables, or known but unmeasured variables, can cause prognostic dissimilarity.

We have mentioned previously that treatment groups in an RCT are only prognostically similar at baseline, and that prognostic similarity can be lost during follow-up. As a consequence, confounding is possible in RCTs, and trial results should be judged in light of this possibility.

Interpretation of Safety Analyses

Safety is considered extremely important in the consideration of whether a new drug or treatment should be approved. A detailed description of the process of drug approval is beyond the scope of this chapter, but there are a few methodologically important issues with regard to the interpretation of safety data in clinical trials. Usually, clinical trials aim at demonstrating efficacy of a drug or treatment. It is important to realize that many relevant adverse events occur in a relatively low frequency and/or (far) beyond the duration of the trial. Consequently, the probability that such a relevant adverse event will occur within the context and time frame of the clinical trial is low, and the interpretation of safety results of a clinical trial does not at all exclude important adverse events. Such information should be obtained through long-term observational studies or drug registries.

Conclusions

The descriptive and statistical analysis of clinical trial data is not an extremely challenging task and should follow the straightforward protocol imposed by the trial design. Universal guidelines are published to guide the investigator, and these guidelines are increasingly warranted by medical journals. This does not mean that interpretation of trial results is always easy and straightforward. We have mentioned a number of disturbing factors that may jeopardize the interpretation of trial results, such as missing data, dropout, and confounding. Investigators as well as the readers of medical journals should be challenged to interpret trial results in light of these potentially disturbing factors.

GENERAL REMARKS

Clinical trials are conducted to test the efficacy of new drugs and devices and to compare the efficacy and safety of combinations of drugs. New drug development is a long and expensive process. The choice of clinical trial design and implementation is critically important for safe, efficient, and successful drug development. Because the cost of clinical trials for new drug development has increased substantially, research leading to regulatory approval of new treatments is done primarily by the pharmaceutical industry

in multicenter clinical trials. Such trials usually are *explanatory* in nature, with internal validity prevailing over external validity. It is widely recognized in medical science that investigator-initiated clinical trials are crucial in studies addressing the effects of combinations of standard drugs, or standard drugs in combination with new treatments, and in initial studies of the effects of drugs newly approved for other indications. Such trials often are more *pragmatic* in nature and have a higher level of external validity (generalizability). Important contributions in the field of investigator-initiated pragmatic RCTs have been published in the rheumatologic literature.²⁶⁻²⁸ It will be a considerable challenge to fund such trials in the future; this need may provide an opportunity for collaboration between academic clinical scientists and the pharmaceutical industry.

The clinical trial is not the only type of clinical research study. An important drawback of clinical trials is that the duration is short, and as a consequence, investigators have to rely on intermediate or process measures for outcomes, rather than the “hard” outcomes themselves. Longitudinal practice-based observational studies may fill in a gap in that they provide important information about the effects of a new treatment when used in diverse groups of patients, about drug toxicity, and about the long-term effects of a treatment on functional status, morbidity, and mortality. They may provide a wealth of information about the relationships between process or surrogate measures and “true” outcome measures. They also may provide useful information about prognostic factors for a certain outcome. A general judgment about the effectiveness of a particular treatment is in the end a compilation of impressions obtained from various sources, including explanatory drug registration trials, pragmatic trials better meeting the needs of clinicians, and observational studies with a focus on “true” outcomes and long-term safety.

Assessment of Health Outcomes

DORCAS E. BEATON • MAARTEN BOERS • PETER TUGWELL

KEY POINTS

Any single health outcome can only provide a particular view of the impact of a disease on a person.

Core sets are minimal, but not exclusive, domains of outcomes agreed upon by professional groups as important to include in studies. They are available for several rheumatologic conditions.

Defining the measurement need is the key to the choice of the right instrument.

Choosing an instrument follows a step-by-step process—looking for evidence of practical aspects of using the instruments and methodological/statistical properties.

If an instrument lacks evidence of a certain property, one can conduct a study to create the evidence rather than abandon the instrument.

In an era of rising health care costs, greater provider accountability,¹ and an increased emphasis on decision making based on patient-reported outcomes,^{2,3} the capacity to discern the best outcomes and the best instruments has become a skill needed by researchers, clinicians, and funding bodies. By one definition, health outcomes refer to “all possible effects of a disease or intervention,”⁴ in our case for a disease like arthritis and the end points used to evaluate its treatment. In addition, there are biomarkers that “mark” a biologic process (e.g., decreased inflammation) and have some relation to health outcome. In a few instances, biomarkers can be regarded as surrogate outcome measures where the relationship with outcome (and change in outcome) is strong, and interventions that target the biomarker result in improved health outcome.⁵ Other chapters in this text refer to some of the most common instruments of health outcome and disease encountered in rheumatology such as the Disease Activity Scale (DAS, DAS28),⁶ the Health Assessment Questionnaire (HAQ),⁷ and the SF-36.⁸ Many more instruments of this type exist, but how different are they? Why do we need to choose so carefully? Using any one of these health outcome assessments is like looking out a window in a house, and the burden of arthritis is the landscape outside. From any one window there is a view of the outside world, but it is a specific view defined by the size of the window and the side of the house it is on. Another window may offer a slightly better perspective on what one would like to see. Different health outcome assessments can have a degree of overlap in their views, in which case an informed choice will need to

be made between them, whereas others can hold quite distinct views. Although one outcome assessment might be useful to compare the burden of arthritis against the general population, another might be better for measuring the specific benefits of an arthritis intervention. No one instrument fulfills all requirements. To carry forward the metaphor of a window, once it is clear whether that instrument can offer a view of the target concept, one must also make sure the view is clear, precise, and consistent each time any person looks through that window—attributes that are shown by the validity and reliability of a scale. This chapter focuses on describing the different windows we have on the burden of arthritis and how they relate to each other. We then provide a framework for ensuring that a selected instrument is the right one for a given need. This chapter therefore addresses three questions: Which health outcomes assessment instruments are available, both generally and specifically, for use in rheumatology? How does one know what one needs to measure? How does one find an instrument that can meet that need?

WHICH HEALTH OUTCOMES ASSESSMENT INSTRUMENTS ARE AVAILABLE?

In reading the rheumatology literature and in monitoring the clinical care of patients, certain highly relevant outcomes will emerge. A group of these often emerges and are called “core sets” of outcomes.

Disease-Specific Instruments: Core Sets

Core sets are the minimal, but not exclusive, set of domains to be measured in a study of arthritis. Historically, they follow the *Ds* of outcome measurement in arthritis: disability, disease activity, damage, discomfort, dissatisfaction, and death.^{9,10} They are usually recommended by groups such as Outcome Measures in Rheumatology (OMERACT), the European League Against Rheumatism (EULAR), International League of Associations for Rheumatology (ILAR), and American College of Rheumatology (ACR) or by groups formed around specific diseases such as the Assessment for Ankylosing Spondylitis (ASAS) and the Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA). All have an interest in agreeing on a common set of relevant and psychometrically sound outcomes that would allow them to compare findings across studies and modalities of clinical care. [Table 33-1](#) shows core sets for clinical trials in nine types of arthritis.¹⁰⁻²⁴ It also shows what each group recommends as additional

*The left-hand column is the broader set of measures recommended by Wolfe and colleagues¹⁰ for longitudinal studies. It serves here as a broader range of outcomes and an axis for the organization of core outcomes in the other conditions (columns).

Osteoporosis: Core set depends on focus: BL, bone loss studies; t, studies aiming to reduce fracture rates.

Ankylosing spondylitis: Core set elements that vary depending on focus of study: † clinical records and symptom modifying; § disease modifying only; others = all.

✓, core domain; DAI, disease activity index; EULAR DAS, European League against Rheumatism Disease Activity Scale (revised = DAS-28, 28 joint count); HCU, health care utilization; O, optional outcome; R, recommended for further research and possible inclusion in core set.

domains or as needing more research before they become core set members. Some groups such as systemic sclerosis are moving through the refinement of their core domains.²⁵ The first column in this table represents Wolfe's broad core set for longitudinal observational studies in rheumatology¹⁰ with some minor additions. Wolfe and colleagues' list is longer than the other columns because observational studies are often looking for a broader range of outcomes than treatment trials. It is also designed to be used across different forms of arthritis. The Wolfe set therefore serves the broader list of outcomes against which we can describe what is also included in the more focused core sets. The remaining columns show that across different types of rheumatic diseases, the core sets have many common elements—most contain or recommend pain, physical function, patient and clinician global assessments, and markers of inflammation. Many also include disease activity and/or damage indices, which are often an aggregation of other clinical findings (e.g., joint count, acute phase reactants, global ratings of severity) into a score reflecting the activity of the disease at that point in time. Some core sets contain domains reflecting the unique aspects of the disease (e.g., spinal mobility in ankylosing spondylitis)²⁶ or the unique target of the study (e.g., tophi in measuring response in gout).²³

Table 33-1 focuses on the core domains that should be measured. The next step is to decide on the instrument(s) that will be able to provide that information in a reproducible, accurate manner. In some cases an instrument choice has been suggested (e.g., the HAQ for disability in rheumatoid arthritis [RA]). In other instances, several options are provided. Strand reviewed six disease activity indices in lupus and found that they gave comparable results.²⁷ In some cases, the domains are shared but the measurement technique varies within or by disease—in RA the DAS28 uses 28 joints,⁶ whereas in ankylosing spondylitis 44 joints are counted.²⁶ We briefly review some of the more commonly encountered instruments in arthritis.

Health Status/Quality of Life

General Health Status. Generic health outcomes provide information on an aspect of health across many conditions, so theoretically comparisons can be made to compare the burden of low back pain with that of arthritis or diabetes. This depends on how well an instrument captures the burden in a disease group. Generic instruments have the advantage of allowing comparisons across diseases and covering a broader range of health issues, which may otherwise be overlooked in a core set (e.g., mental health). However, generic instruments, due to their breadth, tend not to delve sufficiently into the depth of experience in any one disease. Arthritis-related fatigue, for example, is not picked up well in many generic instruments because they ask about “being tired” or “not sleeping well,” rather than the pervasive nature of exhaustion described by patients with arthritis.²⁸ As a result, they are usually weaker in their ability to detect specific changes and their sensitivity to different levels of disease activity may be low. They should, therefore, usually be supplemented with disease-specific instruments.²⁹

Two of the more commonly used generic instruments are the Sickness Impact Profile (SIP)³⁰ and the SF-36 (short

form, 36 items).³¹ The SIP is a 136-item list of illness behaviors that provide a weighted score for the impact of a disease across 12 categories such as bodily pain, work and role functioning, and dressing,³⁰ which lead to global scores as well (physical, psychosocial, and overall). The SIP has been shown to measure illness across a wide variety of health conditions.²⁹ The SF-36 is a 36-item questionnaire of which 35 items are used to obtain 8 domain scores including physical functioning, mental health, role functioning, and pain. It is scored on a 0 to 100 scale (100 = better health)³¹ and two summary scores (mental and physical) that are scored with a normal of 50 and standard deviation of 10. The SF-36 and the briefer SF-12 are supported on the website www.qualitymetric.com and through manuals that supply age- and disease-group distributions of scores.³² Direct comparisons of generic instruments have shown differences in scores and health states attributable to the choice of instrument.³³⁻³⁵ Studies or clinical results may not be comparable with each other if they are using different health status scales.

Utilities: Value of Health State. Utility scales offer an overall score for the value of a health state, setting death at zero and full health at one. The emphasis is not on describing the state but on assigning a value, worth, or preference to that state.^{36,37} Utilities are necessary for economic appraisals and form the health assessment for cost per (quality-adjusted life years) QALY estimations. Utility states can be obtained by direct or indirect methods. Direct methods such as standard gamble and time trade-off involve the respondent working through exercises to elicit the value for his or her own health state against elements like time, or more/less favorable health situations.³⁶ Indirect methods capture the state with standardized questions and then apply predetermined weights.³⁷ Examples include the EQ-5D, which comprises five items (three response categories) combined to describe a health state. Similarly, the Health Utility Index (HUI) gathers information on six or seven dimensions of health (depending on the version) on five-item to six-item response scales to define a health state.³⁷ Both forms, along with the increasingly popular Short-Form Six-Dimensions (SF-6D) utility index,³⁸ then use weights determined in different populations to assign the value to these health states, hence the “indirect” weighting. The absolute values obtained across these different approaches will vary.^{36,39}

Generic measures of health and utility scores are broad. They often do not perform as well as the more specific measures described in the following sections because they are designed to allow comparisons across different patient groups and need to, therefore, include items that might not be relevant or amenable to change in arthritis.

Symptoms. Pain is usually measured using a 10-cm visual analog scale or a 0- to 10-point numeric rating scale of the intensity of the pain.⁴⁰ These scales, simple instruments, have been well tested and are easily understood by patients. Fatigue is another important symptom, which many patients feel is quite distinct from being “tired.”⁴¹ Teams are recommending either global indices or one of several available scales that were reviewed by OMERACT attendees.⁴²⁻⁴⁴ Work done at OMERACT on the measurement of problems with sleep provides a recent strong example of moving through the concept

of impairment of sleep, defining it, and then focusing on the available scales that capture that concept and definition.^{45,46}

Disability Scales. Physical disability caused by RA or osteoarthritis is often measured using the Health Assessment Questionnaire–Disability Index (HAQ-DI),⁴⁷ which covers 20 items examining different domains of daily functioning. Patients score each item on a 0- to 3-point scale, where 3 represents the greatest disability. Scores are obtained for each domain and then combined for a total score expressed on the same 0- to 3-point scale. Scores are adjusted to a worse health state (a 2/3) if a support is used to complete a task. More details on the HAQ-DI are widely available in print and on the Internet.

Other scales or subscales assess physical function such as within the Arthritis Impact Measurement Scale (AIMS)⁴⁸ and the AIMS2,⁴⁹ as well as measures with even more specific foci such as the Western Ontario and McMaster osteoarthritis index (WOMAC), which is commonly used in hip and knee osteoarthritis⁵⁰ and the AUSCAN (Australian-Canadian) osteoarthritis index for hand osteoarthritis (OA).⁵¹

Disease Process (Activity, Severity)

Core sets often include indices of disease process, which can be divided into activity (inflammatory activity) and severity (overall severity of disease) measures. There are several disease activity indices, the most commonly used being the Disease Activity Scale (DAS)⁵² and DAS28⁶ in RA. A subset of the core outcomes (i.e., acute-phase reactants, joint counts, global ratings) was combined to form a weighted score that provides a score of 2 to 10 (DAS) or 0 to 9 (DAS28). Based on these scores, cutoffs were established to define high, moderate, and low disease states. Until recently the low disease state (DAS28 < 2.6) was considered an indicator of remission of arthritis. This is revisited later. Also recently, new criteria for remission in RA have been proposed. In these, the use of the DAS has been abandoned because it allows significant residual disease activity even at low values.⁵³ Disease activity indices track the level of inflammatory activity. Other examples of disease activity indices include the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI)⁵⁴ and the six available for lupus.²⁷ When more than one is available, it is helpful to seek direct comparisons of instruments such as that performed by Strand to evaluate comparable information.^{27,55} Work is also under way to focus on an evidence-based, consensus-driven definition for a flare or worsening of arthritis⁵⁶ to use in clinical trials to describe a worsening rather than improving situation.

Damage Indices

Damage indices are indicators of structural damage to joints, typically shown by joint space narrowing, erosions, subchondral cysts, or osteophytes. In RA, particular attention has been paid to this by van der Heijde, who reviews three approaches (Sharp, Larsen/Scott, and van der Heijde) that are used to assess joint damage and progression in joint damage.²⁶ Progression is usually measured using the “smallest detectable change” that is determined by the threshold

or error associated with the amount of variability in radiographic measurement between observers.^{57,58}

Toxicity/Adverse Events (Wolfe’s “Disadvantage” Category)

Medical and nonmedical management of many rheumatic conditions carries a risk of toxicity and adverse events,⁵⁹ many of them unexpected. Because patients, clinicians, and policy makers want to balance benefits versus harms when considering intervention, comprehensive documentation of a range of adverse events is important in outcomes assessments separate from the treatment benefits.⁶⁰ An OMER-ACT group is currently working on standardizing reporting of toxicities in rheumatologic trials.^{61,62}

Death

Arthritis is associated with increased mortality, and arthritis-specific mortality should be monitored. Death is not specifically mentioned in the disease-specific core sets for clinical trials because the latter are too short-term, but deaths would be important to monitor in observational studies. Attributing death to arthritis is challenging given its dependence on documentation at time of occurrence, which may or may not be linked to underlying arthritis in the coding of cause of death.

Dollar Costs

Given that resources are always limited, together with the benefits and harms, the costs (e.g., dollar costs) of a treatment are also considered an important outcome. Harmonization is important in order to get a comparable estimate of cost across studies.⁶³ Several groups are working toward developing a formula for quantifying the costs associated with arthritis and with its treatment at the time of writing.

Other Outcomes of Interest

Self-Efficacy/Effective Consumer

Self-management is becoming incorporated into programs for persons with many chronic conditions. For patients with arthritis, these programs have been shown to improve levels of self-efficacy; that is, the confidence one has in one’s ability to manage pain and disease effectively. Lorig’s Self-Efficacy Scale is one of the most commonly used outcomes for this type of study.⁶⁴ Tugwell’s group has developed a companion to this, the “effective consumer scale,” which captures the degree to which the patient is effectively managing his or her own health care decisions, interactions with the health care team, and disease monitoring.⁶⁵ It is an instrument with demonstrated reliability, validity, and responsiveness in arthritis⁶⁶ and has the support of consumers with arthritis.⁴¹

Work Disability: Looking beyond Absenteeism

With the shift toward more aggressive management of earlier rheumatic disease, more people with arthritis are

working and outcomes need to shift to track work disability more comprehensively (absenteeism and at-work productivity loss).^{10,41,67} Work is difficult to measure because it depends on the job and the organization in which an individual works. Absenteeism can mean many things, and instruments should articulate how it is operationalized such as full days off work, days on insurance payments, or partial days off work. More challenging still is measuring the difficulty someone is having at work (presenteeism). In a recent review we found more than 20 instruments available.⁶⁸ The most commonly used in arthritis is the Work Limitations Questionnaire (amount of time experiencing difficulty⁶⁹). Two scales developed in arthritis are promising: Gignac's Work Activity Limitations Scale⁷⁰ (amount of difficulty experienced) and Gilworth's Work Instability Scale (captures risk of future work loss).⁷¹ The Work Productivity Scale for Rheumatoid Arthritis has been used in clinical trials and captures worker productivity on a global index, as well as nonpaid work (see next section).⁷²⁻⁷⁴ Direct comparisons of instruments show differences in their performance that primarily relate to the variant of the construct they are measuring.⁷⁵

Nonpaid Work Roles

Participation in valued nonpaid roles such as parenting, volunteer work, or leisure activities can be important aspects of the burden of disease.⁷⁶ Outcome instruments reflecting this are necessary in order to fully capture the concept of participation as described by the International Classification of Functioning (ICF).⁷⁷

Patient-Specific Indices

Patient-specific scales including the MACTAR or PET in arthritis^{78,79} allow the patient to nominate his or her own scale content within a guided framework. Most patients report three to five items that are particularly salient to them. A surprising number of these scales have been developed.^{80,81} Each taps relevant content for patients, and because of this they are also responsive to change.⁸² The challenge is in the mathematics and how to analyze the numeric score that is so dependent on each individual's own items across patients (group level mean or average score has little meaning). Analysis that focuses on individual level quantification is likely best (e.g., percent of people reaching their goal, improving in their selected activities).

Satisfaction with Health Outcomes

Satisfaction scales are often linked with the goals of a health care organization and focus on the attributes of the structure and process of care (e.g., length of wait, professionalism of staff). However, instruments developed to look at satisfaction with a specific health end point (i.e., how satisfied are you with the results of your surgery?)⁸³ become a health outcome. Satisfaction with outcome is complex, and Hudak and colleagues remind us of the complex balance between experiences and ability to "live with" ongoing limitations that influence a patient's response.⁸⁴ However, it may be worth the effort in order to report all outcomes that are meaningful to the patients.

HOW TO DETERMINE WHAT TO MEASURE: DEFINING ONE'S MEASUREMENT NEED

Just as investigators define a research question before embarking on a clinical trial, so should users of health outcomes define a measurement need before choosing an instrument. There are three parts to this definition: what, why, and in whom?

What Is Worth Measuring?

It is important to have a sense of the concept one wants to measure before choosing an instrument. Taking this approach ensures that an appropriate instrument can be chosen and the user will be less swayed by the concept offered by an available instrument.

Defining a need is not always as easy as it might seem. What is health? What about pain? In recent years, there has been a shift in the outcomes toward a more patient-centered focus both from a health systems and political point of view, reinforcing and, indeed, legislating the importance of patient-centered care and outcomes.^{2,3,43,85}

With such a focus, the role of patient as partners in research and outcome definition becomes even more important. Partnerships with patients have opened many doors to improved outcome measurement. There is no better source of information on the nature of a symptom experience or the impact of arthritis on something like work⁶⁷ or fatigue.⁴⁴ The patient experience of disease can complement that of the researcher. The idea is that research grounded in relevant clinical need, patients' perspectives, and patients' priorities will enhance study design, practicality, recruitment, data interpretation, and dissemination. In addition, the reporting of the research results will most likely be more meaningful to patients because it will be done in terms that the patient understands and that are relevant to the patient.^{3,86} In outcome measurement, rheumatology has been in a leading position since the inclusion of patient partners (as experts in the experience of arthritis) at OMERACT conferences from 2002 onward. Perhaps the most concrete example of the impact of the patients' perspective has been the recommendation by OMERACT to include the measurement of fatigue in the core set of measures for clinical trials in RA.⁴⁴ Subsequently, work has focused both on other important aspects such as measurement of sleep quality and more method-oriented topics such as how to rigorously develop new patient-reported outcome measures. Groups such as EULAR or the U.S. Food and Drug Administration have made the involvement of the patient in the development of patient-reported outcomes an essential feature for new scales⁶⁰ (e.g., as seen in the development of RAID [Rheumatoid Arthritis Impact of Disease]).⁸⁷ Involving patients in research has several challenges that include practical issues such as overcoming access, communication barriers, establishment of a new professional relationship while continuing in a doctor-patient relationship, confidentiality issues, and training in science methodology and nomenclature.⁸⁸ It is expected that patient or consumer involvement will become a standard feature in clinical and outcomes research and that methods of engagement will continue to evolve.

Defining key concepts or outcomes may also be facilitated through use of conceptual frameworks. Conceptual frameworks offer definitions of their key concepts and discuss how a construct relates to other variables in their model. One increasingly popular framework is the International Classification of Functioning (ICF) endorsed by the World Health Organization in 2001. The ICF framework (Figure 33-1) describes three main concepts: impairments (symptoms, structural limitations); activity limitations (difficulties while performing tasks); and participation restrictions (social role participation). Also important are environmental factors (e.g., job demands, environmental barriers, weather) and personal factors (predispositions, coping strategies). Other frameworks include the Verbrugge disablement process, which has slightly different concepts along its main pathway,⁸⁹ and the Wilson and Cleary framework.⁹⁰ Both of these frameworks define a main pathway from cellular findings to a broad level of disability or quality of life. Personal and environmental factors are also present in these models, but more as effect modifiers rather than as an essential part of the concept. Importantly, they also differ from the ICF in terms of the definition of “disability,” for example, reinforcing the need to be explicit about not only the concept but also the framework from which one’s definition comes. An alternative definition for physical functioning at the level of disability is described by Verbrugge.⁸⁹ Similarly, when measuring pain, is intensity more important than frequency to patients? What about the degree to which pain interferes with daily activities? Conceptual frameworks define the realm of outcomes that should be considered and the hypothetical relationships between them. They form the basis for understanding our observations, testing hypotheses, or planning and executing an analysis. Choosing a framework that helps one to define and think about the concept one wants to measure will be helpful down the road when trying to understand the findings. Working across different frameworks or trying to fit an instrument into another framework is challenging because different instruments may vary in how they define certain aspects of health or disability. However, shifts to a new framework can prompt fruitful rethinking of concepts and how they relate to each other.⁹¹

Thinking about a concept and defining it carefully and explicitly should precede reviewing any instruments or

core sets. The instrument should meet the need—not the reverse.

Why Measure?

Clarity about an instrument’s intended purpose will help ensure the right one is selected. Kirshner and Guyatt describe three purposes: descriptive (measure a concept at one point in time such as the burden of illness), predictive (provide information about the future such as the HAQ predicting mortality in arthritis), and evaluative (measure change over time such as the benefit or harm from treatment).⁹² Each purpose requires evidence of certain measurement properties of the candidate instrument. In this chapter we focus on the purposes relevant to health outcome assessment: describing an end point state in a trial at one point in time (Kirshner’s descriptive purpose) and evaluating the amount of change experienced over time (Kirshner’s evaluative purpose). The purpose dictates the type of evidence to focus on when making a decision about a given instrument.⁹²

Who Comprises the Target Population?

The target population is critical but often overlooked. A given instrument may, for example, work well in severe OA of the hip but not be sensitive to the early symptoms of the disease. It is equally important to consider if one wants to measure for an individual patient or describe a group of patients as a whole, for example, in a clinical trial. The former demands much higher levels of measurement properties such as reliability coefficients greater than 0.90 as opposed to a minimum of 0.75 to 0.80 for group descriptions).⁹³

Decisions made based on these three points will help define the measurement need and provide a better foundation for critiquing candidate instruments.

DECISION-MAKING INSTRUMENT FOR SELECTING THE OUTCOME THAT CAN MEET THE MEASUREMENT NEED

The selection of an outcome measure depends entirely on a clear understanding of measurement need. All too often a commonly used instrument is selected rather than looking for one that matches the concept, population, and purpose. Once the measurement need is defined, the users should begin on a decision-making process that helps guide the final decision. Many guidelines that offer more detail than can be provided here, particularly for the acceptable levels of reliability and validity, are available.⁹³⁻⁹⁹ What we describe here is a decision-making process that can be used to assess if a given instrument fits with the articulated measurement need. This process, depicted in Figure 33-2, builds on the work of Law⁹⁹ and the OMERACT filter.⁹⁶ It also highlights key concepts in each area from the published guidelines.

This decision-making process has three key features that deserve mention. Once an instrument has been selected for consideration, the process begins with a clear statement of the measurement need. This is an unavoidable step that comes before any evaluation of candidate instruments. Second, there are many things to be done using what has

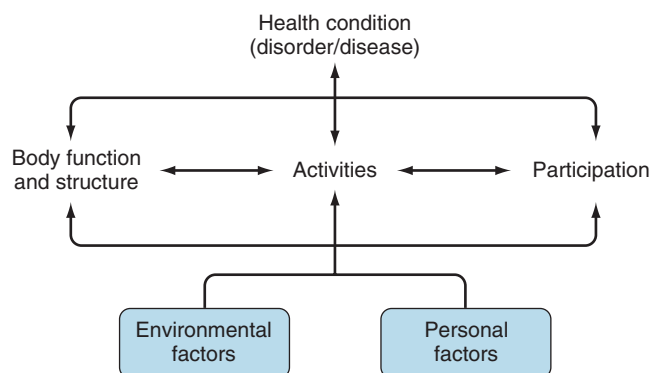

Figure 33-1 The International Classification of Functioning conceptual framework showing the hypothesized relationships between domains of impairment, activity limitations and participation restrictions, and the direct influence of environmental and personal factors on these domains.

Target Measurement need:

Concept _____ Population: _____

Purpose: ☒ one point in time ☒ change over time

Instrument being considered: _____

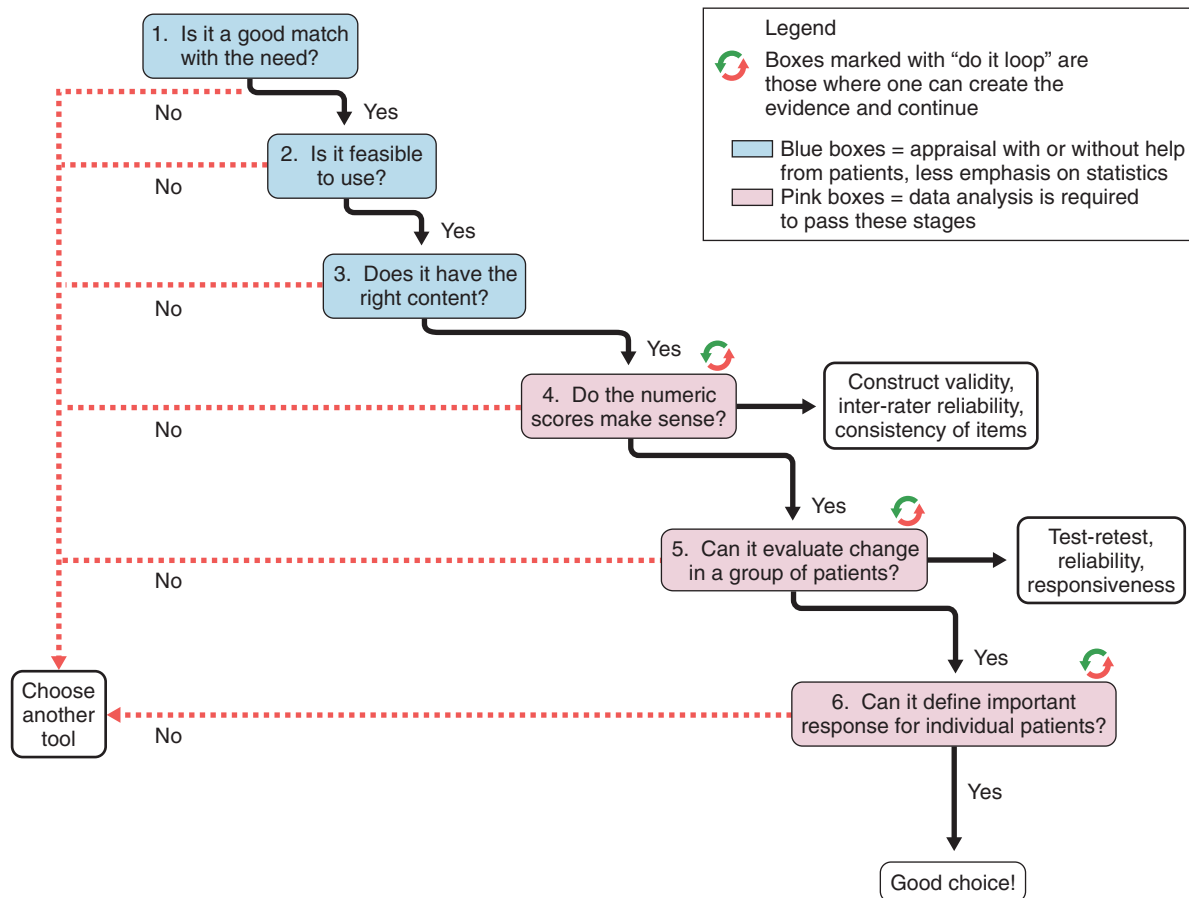

Figure 33-2 Algorithm showing decision-making process for the fit of a candidate measure with a target measurement need. The first three (blue boxes) can be completed by appraisal of the instrument hopefully with input from respondents. The last three (pink boxes) require data. Many instruments are weeded out as a poor fit in steps 1, 2, and 3—things that cannot be corrected. The “do-end” loop denotes stages at which one can pause to create evidence if it is missing, and the instrument does not necessarily have to be abandoned.

been considered a user’s guided reflections on the instrument itself with, if possible, some feedback from patients before looking at correlations and effect size statistics. Perhaps a common misconception is that measurement is all about the statistics, whereas a lot of it is about common sense. Third, the inability to confirm each of the earlier stages indicates an irreconcilable mismatch and suggests that one is better off finding another candidate instrument. On the other hand, at the later data-based stages, one may choose to run a small study to create the evidence (the “do-it” loops) in a patient population, rather than abandoning the instrument that seems until that point to be a good candidate. With these overarching points in mind, we review the process next.

Step 1: Is It a Good Match with the Need?

Think about the concept and then decide based on the description of the candidate instrument and the nature of

the items whether there is a match between the instrument’s concept and the measurement need (concept, population, purpose). An operational definition of the target concept, the applicable populations (specific patient group or general population), and intended purpose should be articulated by the developer and match the current need.^{60,98,100} If it is not there or if it is not a good match, start with another candidate instrument because this one will not work.⁹⁵ For example, the target might be physical function and the instrument only covers physical function briefly but includes more on emotional and social health and is even in use in the research community. If the concept is not a clear match with the target, pass it by.

Step 2: Is It Feasible to Use?

Feasibility covers the practical aspects of using this scale in the intended setting.^{96,99,100} Does it take too much time? Are the licensing costs too high? Does it require special

equipment? Is it too burdensome for patients (language, literacy, acceptability of questions)? Is it formatted well on the page, and do the responses make sense given the target and the question? Are the questions phrased in a clear and simple manner? Are the necessary scoring instructions available? Are the results of the score easily interpretable? A negative to any of these could direct one to go to another, more feasible instrument. Feasibility often makes or breaks a decision about a candidate instrument.⁹⁶ Others might call this “sensitivity” or “clinical usefulness” of an instrument. Usually the appraisal is completed by the investigator, but more insight can be gained by including patients’ input into the length, difficulty, and burden of the questionnaire.

Step 3: Does the Instrument Look Like It Has the Right Content in Order to Measure What It Is Intended to Measure (Truth 1)?

Over the course of the decision-making process, one will see much emphasis on the truth part of the OMERACT filter.⁹⁶ This level of “truth” describes content validity. Does it appear that the candidate instrument is covering the domains of the concept well, and do the items align in this content? This, like step 2, is usually done by the clinicians or researchers, but patients can also provide valuable insight into ensuring the content is comprehensive.

Content validity appraises the items and domains of a scale, as well as whether the authors have covered the breadth and depth of the concept.⁹³ In other words, are all the important areas covered, and is there enough depth to capture the range of experience of the patients? Face validity is an appraisal of the general direction of the scale; will it hit the target? Are the response options organized in a logical direction for high and low levels of this attribute? Does the scoring make sense?

Step 4: Do the Numeric Scores Make Sense? Are These Scores Behaving in Ways That a “Good” Measure of This Construct Would Behave (Truth 2)?

Having convinced oneself of the content and practical feasibility of this scale, the next step begins the more data-intensive evaluation. One can abandon the item-level critique and begin to explore data to see if the numeric scores arising from the instrument make sense and behave in the same way an excellent instrument of this construct would be expected to behave. Confidence with construct validity should be established regardless of the eventual purpose (descriptive or evaluative). Sometimes it is de-emphasized in evaluative instruments in favor of a more detailed evaluation of change and responsiveness; however, others (including the authors) would stress the importance of making sure one knows what is being measured before focusing solely on change scores.

Construct validity is generally measured by comparisons with other similar scales or related constructs (i.e., high and low levels of pain and function). Theoretical situations are established *before* analysis, the direction and magnitude of the expected relationship are declared, and then the relationship is tested.^{95,100,101} Comparisons should also be

made between groups known to differ (high vs. low severity) or with scales where no relationship is found. Again, this is based on an *a priori* theory checking to see if the candidate instrument behaves according to the theory. These comparisons add to the evidence that the instrument is measuring what it is supposed to measure.⁹⁵ If the evidence is not available or not available for the intended population, one has the choice of abandoning the instrument or conducting a study to create that evidence and then continuing to advance.

Construct validity can also be assessed looking at the structure of a scale. If a scale (or subscale) is set up to measure one construct, all the items should “load” onto that one factor. That is, they should be highly correlated with each other enough that together they seem to belong to an underlying trait like health, pain, or anxiety. We assess this structural validity through approaches such as factor analysis (if the instrument was designed to have multiple items aligning with one underlying trait) or item response theory^{101,102} to see if the items designed to capture consecutive levels of the trait along the continuum are doing a satisfactory job.

At this stage it is also necessary to consider the precision of the measurement. The observed score produced by an instrument should be close to the true score with low error. This is estimated by the internal consistency of a multi-item scale or questionnaire using Cronbach alpha coefficients or Kuder Richardson 20 if the scale is dichotomous (yes/no). Internal consistency is a feature of a scale with many items measuring the same thing. The responses should be similar across items within the instrument. It is not a feature of a scale containing weighted sums of different attributes such as disease activity measures.¹⁰³ The internal consistency reliability can be converted back into the scale score by calculating the precision limits (using 95% limits, the true score is somewhere within $1.96 \times s[1-r]^{1/2}$, where r = internal consistency and s = standard deviation). This identifies the range within which the true score for an individual will reside.

If more than one person will be gathering the data, inter-rater/interobserver reliability should be measured and quantified with an intraclass correlation coefficient (ICC) for continuous measures or a weighted Kappa for ordered categories.¹⁰⁴ There are different types of ICC depending on the model used for the variance estimates. The type of ICC should always be named.¹⁰⁴ The ICC and weighted Kappa measure the comparability of actual numeric scores and are preferred over correlation coefficients that look only for trends and not a direct match in number values. Cutoffs are always challenging, but in general reliability should be at a minimum 0.75^{93,100} for group-level analyses (where analysis is always done for a group of patients, as in the mean score comparisons in a clinical trial). For a description of an individual patient, ICC should be 0.90 to 0.95.^{93,100}

Step 5: Can This Instrument Evaluate Change over Time in a Group of Patients?

After getting a general sense of the construct validity of the instrument, we sometimes want to know if this outcome can measure change over time. This is only important if one is

going to measure *change*. In the original OMERACT filter, this was the “discrimination” component of the information need. Can the instrument discriminate finely enough to detect the change one needs to be able to detect? If the goal is to describe an outcome such as the level of pain *after* a treatment, there may be enough information at step 4, or the researcher may want to check its ability to describe response at an individual level (step 6). Interobserver reliability is important if more than one measurer will be involved in the study. The hallmark of the ability to measure change in a group is twofold: First, do the scores remain the same when the target concept has *not* changed over time (test-retest reliability), and second, when the concept changes, does the score on the instrument change as well (responsiveness or sensitivity to change)?

Test-Retest Reliability

Test-retest reliability requires two administrations of the instrument over a time when *no change* in the target concept has occurred. As a reader of reliability studies, one should feel convinced that no change in the target (e.g., pain, function, disease activity) would have occurred in these patients in this situation.^{94,105,106} Often, people conducting studies of test-retest reliability will set up a clinical situation in which no change should have occurred or they use an external anchor (e.g., is your pain the same as last time?) to find patients who have not changed. Like interobserver reliability, the ICC is the preferred statistic for continuous scores and weighted Kappa, its equivalent, for categorical scores.¹⁰⁴ The cutoffs are the same, and a coefficient can be converted into a “minimal detectable change”¹⁰⁷ $= 1.96 \times s(2[1-r])^{1/2}$, where s = standard deviation and r = test-retest reliability (ICC).^{93,107} Ninety-five percent of people who are stable will have change scores less than this value; hence a change greater than this is not likely to occur in a stable patient, only in a changing one. It thus becomes a lower boundary of meaningful change. Anything below that boundary could be day-to-day fluctuations in scores.

Responsiveness is the accurate detection of change when it has occurred. It is best thought of as longitudinal construct validity. Like construct validity, it depends on an *a priori* theoretic relationship in which the attribute is changing over time (e.g., change in pain over time). Researchers all too often focus on the amount of change picked up rather than the match of the change in the instrument’s scores with the type or amount of change that has actually occurred and was expected in that testing situation. A large change is not useful if a small one was expected—it only suggests error. The amount of change expected in a study of responsiveness should be carefully described and should be a clear match with the intended application (i.e., measurement need).¹⁰⁸ If the goal is to detect change in a clinical trial, then it is important to assess the instrument’s ability to detect the difference in change between treatment and control groups. If the goal is to detect change in a cohort, it might be more useful to examine change in a single group, perhaps in a treatment of known efficacy (e.g., hip replacement) or in those people who rated themselves as improved on an external anchor (e.g., global index of change). Responsiveness is summarized with statistics of signal (change) over noise (error) such as the standardized response

mean (mean change/standard deviation of change), t -statistic (mean change/standard error), or effect size (mean change over standard deviation of baseline).¹⁰⁴ Each can be adapted to quantify the relative change between treatment and control groups.^{82,109} Deyo and Centor also described the correlational approach (correlate change and another indicator of change) and the receiver operator curve approach (various change scores against external “gold standard” that the person changes), where the area under the curve serves as a summary statistic.¹¹⁰ The numeric summaries of responsiveness such as effect sizes or areas under the curve should correspond to the type of change expected (*a priori* theory). A large effect size or area under the curve does not mean an instrument is “responsive.” It should correspond with the change anticipated in the study, small or large. Comparisons of the effect sizes are helpful if different instruments are being compared in the same study as done by Buchbinder⁸² and Verhoeven and their colleagues,¹⁰⁹ who both focused on responsiveness in early RA. Responsiveness is a highly contextualized property, and the same instrument may not be responsive in another situation (early vs. late disease, OA vs. RA).¹⁰⁰

Step 6: Can It Define an Important Response for an Individual Patient?

The final step, often deemed the most elusive,¹¹¹ is the interpretability of the scores. Responder analyses that quantify outcome as the “proportion” improved, recovered, or who have responded to therapy need to have the ability to be interpreted at an individual level in order to classify an individual as responsive or not.⁶⁰

Benchmarking States

At the end of a trial, a patient’s pain is at 2/10 on a pain scale. Is this a good outcome? The meaning of different scores on an outcome assessment is used for classifying people both at the beginning of a trial and at the end (final state). To establish the meaning of the specific values of an outcome score, comparisons are made to other known health states such as severity indices, ability to work, or self-rating as mild.¹¹² Gradually, enough trends might be seen across different scenarios to gain confidence in the meaning of “good” or “mild.”^{113,114} In rheumatology, we see the emergence of low or minimal disease activity states (LDAS; MDA),¹¹⁵⁻¹¹⁷ patient acceptable symptom states (PASS),¹¹⁸ or remission criteria with the DAS28⁵⁵ as thresholds below which people are considered to be in an acceptable state (defined as either tolerable symptoms or disease activity that does not require medication changes). At this point these thresholds are being established, and similar to change thresholds, one may find variability in the values⁵⁵ that will need to be sorted out with methodological work and application in clinical practice.

Changes in State

The second type of interpretability concerns change scores. **American College of Rheumatology Response Criteria.** The American College of Rheumatology took the core set

measures and determined that if one observed an X% change in joint count and swollen joint count and in at least three other areas—erythrocyte sedimentation rate or C-reactive protein, physician global, patient global, pain, or physical disability—one had a clinical response, and the individual would be classified as a responder. The percent is usually 20%, but 50% and 70% have also been considered. The ACR20 is widely used, defining responses across a wide variety of domains, and discriminates well in clinical trials¹⁰⁹; however, it is currently being revalidated due to the changing nature of RA and its care.¹¹⁹

Minimal Clinically Important Differences/Improvements. Defining the threshold of change above which a person has had an “important” shift in outcome is what Kirwan has described as the “elusive crock of gold at the end of the rainbow.”¹¹¹ Nevertheless, important advances have been made. In 2000, Wells and colleagues described nine different methods for deriving minimal clinically important differences (MCIDs) from the literature.¹²⁰ Some use distributional cutoffs (e.g., $\frac{1}{2}$ standard deviation, effect size of 0.2 or 0.5),¹²¹ which have been criticized as lacking any meaningful anchor. Others depend on an external anchor, indicating that important improvement has occurred, but are sometimes challenged by their dependence on that anchor, as well as on the perspective of the person who determines the response (patient, doctor, third-party payer). MCIDs have been shown repeatedly to vary with baseline state^{122,123} and with improvement versus deterioration.¹²⁴ Tubach and colleagues have changed the term to *minimal clinically important improvement*¹²⁵ and only looks at improvement. MCIDs vary depending on the context of measurement. Plan on working with a range of values,¹²⁶⁻¹²⁸ make sure the measurement situation is similar to your own (e.g., severity, timing, type of intervention), and build confidence with congruence in MCIDs from across methods if you can achieve that.

Combined Approaches: Change and State

An attractive, though often overlooked, option is combining the last two. In 1996 EULAR defined clinical response as a change in DAS28 score of more than 1.2 (change), plus a final DAS28 score of less than 2.4 (final state).⁵² Jacobson and colleagues¹²⁹ did the same in defining response to psychotherapy; change greater than error was used (minimal detectable change mentioned earlier) plus a final “normal” state. Studies from the patient’s perspective have often reflected the same thing.^{113,114,130} Treatment needs to induce a change, but perhaps it also needs to land people in a healthy state such as feeling better or being able to do their daily tasks.

The approaches described earlier focus on interpretation at the level of the individual, perhaps for use in clinical practice or in a response-type analysis of a clinical trial or economic appraisal (% responder). Verhoeven and colleagues¹⁰⁹ have shown that the same instrument may not perform equally well in a responder-type analysis and for a group-level change.

At each stage of this appraisal, there is an element of judgment. Perfect evidence across all stages will never be likely. The user will need to assess the potential risk of accepting less than ideal evidence or abandoning the scale.

They may also, however, *create* the evidence by doing it themselves. An instrument that makes it through this appraisal is likely a good fit with the measurement need. Anything short of that could lead to error and be prone to misinterpretation. By working from left to right on the figure, instruments that are not targeting the right concept or are impractical to use in the intended setting can be quickly eliminated before extensively reviewing the literature for the measurement properties.

AREAS OF GROWTH IN HEALTH OUTCOME ASSESSMENT

Item Response Theory

Traditional instruments have often been developed using either classical test theory (psychometrics) or a regression on key clinical findings (e.g., prediction rules, diagnostic or disease activity scores). However, other methods take another approach to instrument development. For example, instrument development may employ a modern measurement theory such as item response theory (IRT). Using IRT, one might choose a different set of items because this approach favors items representing the whole range of a concept (e.g., pain, disability). In contrast, classical tests tend to favor items that are highly correlated to one another, sometimes not favoring items at the extremes. Instruments developed or scored using IRT will still need to demonstrate validity and/or responsiveness, as well as reliability, but an IRT person score will be used rather than a summed score based on observed item responses. The advantage of IRT is that items are ordered from those representing low levels of the attribute to those representing high levels. Computer-based scoring can then skip items that do not need to be asked based on previous responses. This streamlined testing can allow a precise estimation of the level of that attribute using fewer items.

This type of streamlined scoring is attractive, but there are some limitations. Different patients are being assessed using different outcome questions, each targeting their level of health. It is a method that depends on technology which may not at this time be available in every setting. It may also be influenced by differential item functioning (dif), which means an item might change weight or order in certain subgroups of patients and necessitates more complex weights. An example of dif would be putting on a sweater or shirt over one’s head: It is a difficult task with shoulder pain but easy with a hand problem. This would require a different weight in each group.

The National Institutes of Health is currently funding “PROMIS” (Patient-Reported Outcomes Measurement Information System: www.nihpromis.org/) to develop a computer adaptive testing system (currently based on two-parameter graded response model IRT) for the more common chronic diseases including arthritis.¹³¹ Several instruments have been pooled into a large database and are being refined and rescaled at the time of writing. Well-known instruments such as the HAQ have also been used to allow for cross-calibration with the newer items.^{41,132} All findings and scoring algorithms will be reported on the PROMIS website.

Adaptation to an Ongoing Disease

In this chapter, we have focused on the measurement of health states and, indeed, their improvement or deterioration over time. However, people with chronic diseases will adapt to ongoing disease with behavioral strategies, or cognitive reframing of their situation.¹³³ In some circles this is called *adjustment*,¹³⁰ and in others it is called *response shift*.¹³⁴ The challenge in health outcome assessment is to tell when a state is changing only because of adaptation and not the intervention. In many situations we try to induce adaptation, or cognitive reframing, and it can be constructive. It can, however, create a bias in measurement¹³⁴ and a challenge to the health outcome assessor. A number of groups are researching how to incorporate adaptation into our health outcome assessments.

Changing Nature of Clinical Trials

Outcome measures provide critical yardsticks for clinical trials, yet there are many changes in the face of clinical trials. There are more pragmatic trials, comparative effectiveness studies, and nonpharmacologic trials that will demand more precise, sensitive measures of treatment benefits because they will by design have smaller relative effect (treatment vs. control arms). Further, researchers are hearing the need for different disease and outcome targets and must respond to the call for strong measures of coping, self-efficacy (including efficacy as a health consumer), and the impact of arthritis on a person's life.^{41,43}

CONCLUSION: ARE WE THERE YET?

There is considerable room for improvement in health outcome assessment in rheumatology, despite the work done to date. We have developed a battery of instruments, many of which are demonstrating the measurement properties described earlier and facing the challenge of a changing arthritis target (less severe, earlier disease), and we are considering several more measures for membership in core sets in order to capture a comprehensive view of the burden of arthritis. We are on the brink of deciding on the role to be played by item response theory and computer adaptive testing in widespread care settings. However, despite progress in assigning a numeric value to a complex health state, we now are in a healthy struggle with the back-translation—what does the numeric score mean in the real world of the patient-clinician decision making? It is not always a simple translation from questionnaire score to clinical meaning. Health outcome assessment is well advanced in arthritis care, and we should recognize the years of work and commitment of many professional and patient/consumer groups. Advances will continue in the use of technology, the breadth and depth of our outcomes, and the quality of measurement to keep pace with the needs of patients, clinicians, and researchers.

Acknowledgments

Dr. Tugwell holds a Canada Research Chair in Health Equity. The authors would like to thank Dr. Claire Bombardier, Dr. John Kirwan, Dr. Sarah Hewlett, Ms. Ellie Pinsker, Ms. Patricia Nedanovski, and the OMERACT executive for their help with this manuscript.

KEY POINTS

Uniform definitions of disease are essential for biomarker validation and comparison among studies.

The validation process of a biomarker depends on the specific purpose of its use.

For tissue homeostasis, the balance between anabolic and catabolic process is important; extracellular matrix remodeling biomarkers should reflect these different processes.

Understanding tissue source, formation, and clearance of a biomarker is important for correctly interpreting biomarker data.

Analyses of serial synovial biopsy specimens can potentially be used as a screening method to test new drug candidates requiring relatively small numbers of patients.

Panels of biomarkers or biomarker profiles are potentially more powerful than single biomarkers.

For biomarker identification, validation, and application, use of patient subclassification/stratification is essential to increase homogeneity in study and treatment groups.

Biomarkers are anatomic, physiologic, biochemical, or molecular parameters associated with the presence and severity of specific diseases and are detectable by a variety of methods including physical examination, laboratory assays, and imaging. Here the focus is on biomarkers *in senso stricto*: markers that can be measured in patient samples such as blood, urine, synovial fluid, and synovial tissue. Such molecules often first appear in studies on disease mechanisms, their application as biomarkers being secondary. Realizing the importance and potential of biologic markers, the identification, characterization, and validation of novel biomarkers is often a primary objective in many current studies. Biomarkers are applied for various purposes including diagnosis, prognosis, monitoring of disease progression, selection of patient populations in clinical trials, assessment of the efficacy of treatment, or unraveling of the pathobiology of a disease in the clinical and in a preclinical setting. More recently, biomarker validation level-of-evidence schemes have been proposed to optimize efficient use of biomarkers in these diverse research areas.^{1,2}

For osteoarthritis and rheumatoid arthritis (RA), the most important common feature is progressive destruction of articular tissues, resulting in impaired joint function and pain. Diagnosis is based on clinical symptoms and laboratory tests in combination with radiography, to visualize often irreversible degenerative and destructive changes in

the joint. Radiologic evaluation of joints mainly images bone and is relatively insensitive: A follow-up period of at least 1 year is necessary to assess disease progression and effect of therapy. Magnetic resonance imaging (MRI) has the ability to visualize all joint tissues simultaneously; it is currently being optimized³ but has yet not reached its full potential due to its relatively high cost and still limited availability.⁴ Except for imaging modalities such as positron emission tomography scans, which use labeled tracers that may be used to image an ongoing biologic process, most imaging techniques provide a cumulative historical view of damage that has already occurred, rather than assessing the current rate of disease progression (Figure 34-1).

Alternative methods that detect changes in the joints in an early stage of the disease in a quantitative, reliable, and sensitive manner are necessary. The World Health Organization in its report *Priority Medicine for Europe and the World* states that biomarkers are essential for arthritis in general and osteoarthritis research in particular, and that the lack of adequate markers constitutes a major hurdle for osteoarthritis drug development.⁵ No osteoarthritis biomarker underwent the formal approval procedure of the U.S. Food and Drug Administration (FDA) to be allowed as qualifying end point in a phase III clinical trial.⁶ Molecular markers (i.e., markers that are used to monitor molecular events occurring during disease) are well suited for this purpose. A good marker is disease specific, reflects actual disease activity, is sensitive to change after therapy, and can predict disease outcome. Most likely, all of these requirements are not met by a single marker: Different (combinations of) markers would have to be applied for different purposes. The fact that imaging techniques often focus on one joint (e.g., knee or hip) or joint group (e.g., hands, lumbar spine), whereas urine-derived or blood-derived biomarkers are determined by all of the joints in the body, further underscores the importance of using imaging and biomarker approaches as complementary tools. The molecular markers that are described for joint diseases can be arbitrarily classified as follows:

1. Immunologic and inflammatory markers (including acute-phase proteins)
2. Markers that reflect extracellular matrix remodeling (Table 34-1)
3. Markers present in synovial tissue biopsy specimens
4. “Omics”-based biomarkers (e.g., genomics, transcriptomics, proteomics, metabolomics)
5. Genetic markers that have been shown to provide important information on risk factors for development and progression of osteoarthritis and RA; these are reviewed elsewhere⁷⁻¹⁰ and are not included in this chapter.

Figure 34-1 Relationship between radiology and biomarkers. Radiology and magnetic resonance imaging provide a cumulative historical view of joint destruction, whereas biomarkers provide dynamic information on the current rate of joint destruction or disease activity. **A**, At any given time, the slope of the x-ray versus time plot should be compared with biomarker levels. **B**, Consequently, the progression of x-ray damage ($\Delta \text{X-ray}$) must be related to the time-integrated marker levels (area under the curve [AUC]).

INFLAMMATORY BIOMARKERS AND SIGNAL MOLECULES

Extensively studied markers in inflammatory arthritis that are routinely used in clinical practice include acute-phase proteins such as C-reactive protein (CRP) and measurements such as the erythrocyte sedimentation rate (ESR), both of which provide information about the systemic inflammatory process. Although such markers of inflammation are neither disease specific nor tissue specific, they may reflect disease activity,¹¹ reflect the effects of immunosuppressive and immunomodulatory therapies,¹² and, to a certain extent, predict disease progression in RA.¹³ A more disease-specific marker for RA is the presence of anticitrullinated protein/peptide antibodies.¹⁴ It predicts with high probability the development of RA in patients with no clinical symptoms, distinguishes between RA and other rheumatic diseases, and is a valuable tool for prognostic prediction of joint destruction.¹⁵ Although synovial inflammation is often regarded as a secondary process in osteoarthritis, cytokines and other signal molecules have also been proposed as markers in this disease. In clinical studies, often highly sensitive analysis of CRP is included because it is associated with osteoarthritis of the knee^{16,17} and hip,¹⁸ but validation of this biomarker to monitor treatment efficacy is hampered by the lack of effective treatments (as is the difficulty with all osteoarthritis biomarkers).

Cytokines and Chemokines

RA patients often show elevated levels of a variety of cytokines, chemokines, and their receptors (for details see Chapter 26). Many of these molecules are subsequently used as disease biomarkers or studied as targets for intervention, analogous to the experience with tumor necrosis factor (TNF). This cytokine has been shown to play a pivotal role in arthritis and has emerged as a major therapeutic target. TNF inhibitors (neutralizing antibodies or soluble receptors) strongly reduce clinical symptoms, joint inflammation, and biomarkers of inflammation and bone destruction in RA patients.^{12,19,20} Neither the serum levels of the TNF receptors nor those of interleukin (IL)-10 were reduced, however, in response to treatment of RA patients with methotrexate and anti-TNF treatment, despite a clear improvement in clinical disease parameters and a reduction of CRP and ESR.²¹ In contrast, in synovial tissue, treatment with these drugs did reduce the local TNF level, indicating that for biomarker analysis it is important to select the right compartment.²²⁻²⁴ The observation that anti-TNF treatment may block joint destruction in patients who do not show a clinical response (i.e., ACR20 nonresponders) suggests that, similar to osteoarthritis, in RA uncoupling of inflammation and joint destruction may occur, which may affect the selection of biomarkers to monitor treatment effects. High levels of soluble receptors of TNF are associated with reduced physical function and worse radiologic knee osteoarthritis.²⁵

IL-6 is another cytokine that has gained interest in the past few years as a therapeutic target in RA. Anti-IL-6 receptor antibody therapy in combination with methotrexate results in decreased RA disease activity, improved function, and reduced levels of joint destruction biomarkers.^{26,27} Synovial fluid IL-6 levels in RA patients are correlated with infiltration of inflammatory cells in the synovial membrane and with radiographic joint destruction.^{28,29} In a clinical trial of cytokine blockade, baseline serum IL-6 levels predicted radiographic progression, but not the ACR response, again indicating that inflammation and joint destruction are not necessarily coupled in RA.³⁰ Systemic circulating IL-6 levels are well correlated with CRP levels, and therefore the added value of this biomarker seems to be limited for monitoring RA disease activity and response to treatment.^{31,32}

Adipokines

Since the discovery of leptin, white adipose tissue is no longer considered as only a fat storage tissue but also as an active contributor to a wide variety of physiologic and pathologic processes including RA and osteoarthritis. It plays a critical role as an endocrine organ, producing a number of active peptides, the so-called *adipokines*.

The role of leptin in the pathogenesis of rheumatoid arthritis is still under debate.³³ Increased systemic levels of leptin in RA patients compared with controls were observed, and a positive correlation among serum leptin concentration and disease activity, ESR, and the number of tender joints was demonstrated.³⁴⁻³⁶ In contrast, other studies demonstrated a link between leptin and body mass index and not with disease activity.³⁷⁻⁴⁰ In line with this observation is

Table 34-1 Molecular Markers That Reflect Extra Cellular Matrix Remodeling

Marker	Joint Tissue	References
Synthesis		
<i>Collagen Type I</i>		
N-propeptide (PINP)	Bone, soft tissues	58
C-propeptide (PICP)	Bone, soft tissues	58
<i>Collagen Type II</i>		
N-propeptide (PIINP; PIIANP)	Cartilage	75, 102, 103
C-propeptide (PIICP; chondrocalcin)	Cartilage	95, 100, 101
<i>Collagen Type III</i>		
N-propeptide (PIIINP)	Soft tissues	74, 104-106
<i>Proteoglycans and Glycosaminoglycans</i>		
Chondroitin sulfate (epitopes 846, 3-B-3, 7-D-4)	Cartilage	88, 95, 96, 112-116
<i>Miscellaneous</i>		
Bone-specific alanine phosphatase	Bone	58
Osteocalcin	Bone	59
YKL-40 (CYLK-40, gp-39, chondrex)	Cartilage	58, 59
Hyaluronan	Cartilage, synovium	77, 116, 122-127
Degradation		
<i>Collagen Type I</i>		
Cross-linked N-telopeptide (NTx)	Bone	58, 59, 63, 64, 68-71
Cross-linked C-telopeptide (CTx)	Bone	59, 64, 67-71
Cross-linked C-telopeptide (ICTP)	Soft tissues	64, 66
Collagenase cleavage neopeptide (C1, 2C)	Bone, soft tissues	89, 90
<i>Collagen Type II</i>		
Cross-linked C-telopeptide (CTx-II; 2B4 epitope)	Cartilage	59, 73-83
Collagenase cleavage neopeptide (9A4, C2C, C1, 2C)	Cartilage	86-92
<i>Pyridinolines</i>		
Hydroxylsypyrindinoline (HP, PYR)	Bone, cartilage	94-96
Lysylpyrindinoline (LP, D-PYR, DPD)	Bone	95, 96
Glucosylgalactosyl-hydroxypyridinoline (GGHP)	Synovium	75, 97
<i>Proteoglycans and Glycosaminoglycans</i>		
Aggrecan core protein (fragments)	Cartilage	58, 118-121
Keratan sulfate (epitope 5-D-4, AN9P1)	Cartilage	58, 88, 95, 96, 107-116
Chondroitin sulfate	Cartilage	58
<i>Miscellaneous</i>		
Matrix metalloproteinases	Cartilage, synovium	27, 30, 75, 138, 140-152
Aggrecanases	Cartilage	117, 153-159
Cartilage oligomeric matrix protein (COMP)	Cartilage, possibly synovium	74, 128-139
Bone sialoprotein (BSP)	Bone	57, 96

the fact that anti-TNF therapy did not reduce plasma leptin concentrations while inflammation decreased in the patients.⁴¹

Adiponectin is another well-known adipokine secreted by adipose tissue, and serum concentrations are inversely correlated with body mass index. In contrast to its protective role in obesity-linked diseases, adiponectin seems to fulfill a proinflammatory role in RA.⁴² Serum and synovial fluid adiponectin levels are significantly higher in RA patients than in healthy controls, and serum levels correlate with the severity of joint destruction.^{35,43} However, inconsistent data on the effect of anti-TNF therapy on circulating adiponectin levels exist, showing an increased level of

adiponectin after therapy or no effect at all.^{41,44-48} As such, the value of circulating adiponectin for assessing anti-inflammatory therapy seems to be limited.

Other adipokines such as visfatin and resistin have been implicated in the pathogenesis of RA as well.⁴⁹ Visfatin expression is not limited to adipose tissue, but synovial fibroblasts from RA patients also exhibit visfatin expression, especially in the synovial lining and at sites of invasion.⁵⁰ A positive correlation between visfatin serum levels and clinical disease activity has been demonstrated; however, in another clinical study such a relation was not observed.^{50,51} Resistin expression is found in the sublining layer of the synovium and is more intensive in RA than in osteoarthritis

patients. Increased circulating resistin levels in RA patients correlate with both CRP and disease activity.^{52,53}

Although a proinflammatory role is suggested for the previously mentioned adipokines and is sustained by *in vitro* data, clinical data that reveal these adipokines as therapeutic targets or as biomarkers in RA are sparse and contradictory. Further research into the relation of serum/synovial fluid adipokine level and inflammatory markers such as CRP or clinical disease activity such as DAS28 is necessary to evaluate the value of these adipokines as prognostic, diagnostic, or therapeutic biomarkers in RA.

In osteoarthritis patients, serum nitrate and nitrite (reflecting nitric oxide levels) are increased compared with healthy controls, but not as much as in inflammatory conditions such as RA.⁵⁴ In addition, using a genomics approach, chondrocytes from osteoarthritis cartilage have been shown to upregulate the transcription of a variety of inflammatory genes.⁵⁵ Synovial tissue from osteoarthritis patients also shows signs of hyperplasia and inflammation.⁵⁶ Although osteoarthritis is traditionally viewed as a noninflammatory arthropathy, an osteoarthritic joint could be considered a mildly inflamed organ.

The added value of inflammation biomarkers measured in peripheral blood in joint diseases is still undecided. Although the levels of many inflammatory molecules may change in various (stages of) diseases, such change does not mean that the molecule is directly involved in the disease process or is sensitive to change after intervention. Serum cytokine levels often do not predict clinical response. As such, it is crucial to understand the complex biologic networks and the mode of action of treatments to be able to select the right (relevant) molecules to use as biomarkers. In view of this, the ultimate application of inflammation biomarkers in osteoarthritis studies is likely to be different from RA studies.

EXTRACELLULAR MATRIX REMODELING BIOMARKERS

Because of the aforementioned issues, the focus of many biomarker studies is on markers that mirror disease-related changes in the joints, especially markers for remodeling (i.e., degradation and synthesis) of the extracellular matrix.⁵⁷ Concomitant changes may occur in all joint tissues (cartilage, bone, and synovium), and for a comprehensive assessment of these changes molecular markers are necessary for each of these tissues.^{58,59} For the markers derived from these different tissues, there can be a substantial difference in which biologic fluid biomarker levels are determined.

The concentration of markers in body fluids reflects not only the dynamics of the disease but also the rate of clearance and the amount of remaining tissue. Cartilage-derived markers diffuse out of the tissue and enter the synovial fluid, which may vary in volume depending on the severity of ongoing inflammation. Synovial fluid urea levels may be used to correct for this “dilution.”⁶⁰ Clearance from the synovial fluid predominantly occurs via lymphatic drainage, and partial degradation may occur in the lymph nodes, depending on the marker studied. Synovial clearance may depend on the severity of the ongoing synovitis and be determined by the permeability of the synovial membrane

microvasculature.⁶¹ When the marker enters the systemic circulation, dilution occurs (e.g., 5 mL of synovial fluid vs. approximately 5 L of blood), and marker levels are confounded by molecules from other affected, or nonaffected, joints or even from nonarticular cartilage.

Bone-derived and synovium-derived markers may also enter the circulation directly. When the marker enters the systemic circulation, it is diluted, mixed with markers derived from other joints or tissues, and potentially metabolized in the liver and kidneys. Excretion in the urine depends on the marker and the previously mentioned metabolic processes. In the discussion that follows, examples are given from studies of osteoarthritis and RA to illustrate their use in assessing disease-related tissue remodeling.

Collagen Markers

The main constituent of the extracellular matrix of connective tissues is collagen, which plays an essential role in the maintenance of tissue shape, strength, and integrity. Fibrillar collagen types I, II, and III are synthesized as propeptide-containing α chains that are post-translationally modified by hydroxylation of lysyl and prolyl residues and by glycosylation of hydroxylysyl residues. Triple helical collagen molecules are secreted from the cell, the propeptides are cleaved off, and fibrils that are stabilized by intermolecular cross-links are formed. This unique sequence of events provides a variety of tools that are used to study collagen synthesis (especially propeptides) and degradation (especially cross-links) in rheumatic diseases (Figure 34-2).⁶²

In bone, type I collagen constitutes 90% of the organic matrix and markers of bone collagen turnover have proven valuable in monitoring diseases such as osteoporosis.⁶³ For some bone markers such as NTx (bone degradation [see later]) and osteocalcin (bone formation), assays have been approved by the FDA to monitor efficacy of antiresorptive therapies or bone formation, sometimes even as a point-of-care test. For these bone metabolites, there is a significant menopausal effect that requires properly matched control groups and careful interpretation of the data.

Several assays have been used to assess collagen type I degradation in RA and osteoarthritis. The cross-linked C-terminal telopeptide (ICTP) is released by matrix metalloproteinase (MMP) cleavage of type I collagen, and its levels reflect MMP-mediated soft tissue degradation.⁶⁴ The NTx/CTx-I assay and ICTP assay detect type I collagen degradation, but by different proteases. Cathepsin K-mediated osteoclastic bone resorption destroys ICTP antigenicity.⁶⁴ Slightly elevated serum ICTP levels are found in RA compared with controls and are associated with disease activity measured by ESR, CRP levels, and swollen joint counts.⁶⁵ In osteoarthritis, fourfold increased ICTP levels have been detected in patients with rapid progressive hip osteoarthritis compared with patients with slowly progressive disease.⁶⁶

When the C-terminal or the N-terminal telopeptide of type I collagen (CTx or NTx) is released from bone degraded by cathepsin K, an epitope that is different from the MMP-mediated ICTP epitope is generated. In osteoarthritis patients, serum and urinary CTx levels are decreased compared with controls, which suggests decreased bone remodeling in osteoarthritis.^{59,67} In RA, urinary NTx and CTx

Figure 34-2 Collagen-based markers for joint destruction. Collagen is synthesized as propeptide-containing α chains that are post-translationally modified by hydroxylation of lysyl and prolyl residues and by glycosylation of hydroxylysyl residues. These modifications cease when three α chains entwine to form a collagen triple helix. Triple helical collagen molecules are secreted from the cell, and the propeptides are cleaved off extracellularly. Subsequently, collagen molecules spontaneously assemble into fibrils with quarter-staggered overlap of the individual triple helices. Finally, the fibrils are stabilized by formation of intermolecular pyridinoline cross-links. CTx, C-terminal telopeptide (formally: carboxy-terminal collagen crosslink); HP, hydroxylysylpyridinoline; HP/LP, ratio between HP and LP; ICTP, cross-linked carboxyterminal telopeptide of type I collagen; LP, lysylpyridinoline; NTx, N-terminal telopeptide (formally: amino-terminal collagen crosslink).

levels are increased compared with healthy controls and are sensitive to change after treatment.⁶⁸⁻⁷⁰

Although on initial examination CTx and ICTP seem to provide identical information, closer inspection reveals that these two markers, although based on the same principle of detecting type I collagen telopeptides, may provide valuable complementary information. CTx and NTx levels are low in patients with *pyknodysostosis*, which is caused by a deficient activity of cathepsin K, whereas ICTP levels are elevated in this condition. It has also been shown that in postmenopausal women, anti-bone resorption therapy by hormone replacement reduced serum CTx levels, whereas ICTP levels did not change.⁷¹ In cartilage, type II collagen constitutes 80% of the dry weight of the tissue. Damage to the collagen network (collagen degradation and subsequent denaturation) is one of the first features of osteoarthritis and contributes significantly to the decreased mechanical properties of osteoarthritic cartilage.⁷² Using monoclonal antibodies, release of cross-linked type II collagen telopeptides (C-telopeptide, CTx-II) was shown to reflect cartilage degradation with high tissue specificity.⁷³ Urinary CTx-II levels

were significantly increased in RA and osteoarthritis patients compared with healthy controls, although the ranges overlapped considerably.⁷³⁻⁷⁵ In a population-based study, subjects with a CTx-II level in the highest quartile had a 4.2-fold increased risk of having radiographic osteoarthritis of the knee and hip (compared with subjects in the lowest quartile) and a 6-fold (knee) or 8.4-fold (hip) increased risk for progression of osteoarthritis.⁷⁶ In osteoarthritis patients, CTx-II levels correlated with radiologic joint space narrowing and joint surface area but did not correlate with WOMAC indices of clinical status in these osteoarthritis patients.⁵⁹ In patients with hip osteoarthritis, urinary CTx-II levels greater than 346 ng/mmol creatinine were associated with a twofold increase in radiographic disease progression compared with patients whose levels were less than 346 ng/mmol creatinine.⁷⁷ Treatment of these patients with a candidate antiosteoarthritis drug (diacerein) seemed to modulate the CTx-II levels consistent with the effects on disease progression.^{77,78} In a study of patients with radiographic osteoarthritis in multiple joints, there was a significant association between the total

radiographic OA score and urinary CTx-II levels. Subsequent multivariate analysis showed that the joint site-specific ROA score at all joint sites except for spinal disk degeneration contributed independently to this association.⁷⁹

In RA patients, increased baseline CTx-II levels were associated with progression of joint damage, which was independent of baseline damage, treatment, and disease activity.⁷⁵ Other studies also reported that urinary CTx-II is a strong, independent predictor of progressive joint destruction in RA.^{80,81}

In patients with active RA, the decrease in urinary CTx-II levels that was observed 3 months after initiation of treatment predicted the radiographic disease progression over 5 years, suggesting that urinary CTx-II levels may be used as an early marker of treatment efficacy.⁸² Anti-TNF treatment of patients with active RA for more than 1 year resulted in a significant reduction of CTx-II levels in the progressive group but not in the nonprogressive group, although the levels were not significantly different from baseline.⁸³ Additional data on the influence of intervention therapy on CTx-II levels are required to judge whether this biomarker is valuable for assessing efficacy of treatment to halt further joint destruction.

Apart from telopeptide fragments, neoepitopes resulting from the cleavage of type II collagen by collagenases (MMP-1, MMP-8, and MMP-13) have been used to monitor cartilage collagen damage.⁸⁴⁻⁸⁶ Urinary excretion of collagen fragments containing the C-terminal neoepitope (TIINE assay, using antibody 9A4) was increased in osteoarthritis patients compared with age-matched healthy controls.⁸⁷ In synovial fluid, levels of a similar C-terminal neoepitope (C2C epitope, using the Col2-3/4Clong antibody) were significantly higher in osteoarthritis than in RA.⁸⁸ In RA patients, serum levels of these biomarkers (C2C and C1,2C, a similar epitope present in types I and II collagen) were associated with progression of radiographic joint damage.⁸⁹ In a randomized, double-blind, placebo-controlled glucosamine discontinuation trial of 137 subjects with knee osteoarthritis, neither C2C level nor C1,2C level, or their ratio, was affected by the treatment.⁹⁰ Urinary levels of the 622-632 peptide of type II collagen (also known as HELIX-II) were increased in patients with primary knee osteoarthritis (281 ng/mmol creatinine) and RA patients (409 ng/mmol creatinine) compared with healthy controls (180 ng/mmol creatinine).⁸⁶ However, this and other reports^{86,91} applying the HELIX-II assay have to be interpreted with care because due to an apparent database error in the sequence, the epitope used to generate the HELIX-II antibody does not occur in cartilage type II collagen.⁹² Consequently, based on collagen sequences and HELIX-II epitope properties, type III collagen is one of several candidate sources of the cross-reacting signal in body fluids, but not type II collagen.⁹² This example illustrates an intrinsic potential deficit of all enzyme-linked immunosorbent assays (ELISAs), whether in competitive or sandwich format. These assays measure all immune reactivity but do not characterize which peptide binds to the ELISA antibody. Results are therefore potentially confounded by the contribution of additional peptides containing that same epitope but derived from other proteins. Liquid chromatography-tandem mass spectrometry (LC-MS/MS) assays are ideal to

quantify unique peptides from a mixture of peptides. Therefore immune affinity LC-MS/MS assays that capture relevant peptides using an antibody and quantify the peptide of interest using mass spectroscopy combine the best of both assays.⁹³

Collagen Cross-Links

Degradation of fibrillar collagen types I, II, and III results in the quantitative excretion of the cross-links hydroxylysylpyridinoline (HP), derived from bone and soft tissue including cartilage, and lysylpyridinoline (LP), derived from bone, in the urine. In RA patients who received combination therapy (sulfasalazine, methotrexate, and prednisolone in the COBRA trial), time-integrated urinary HP levels correlated with the progression of radiographic joint damage (Sharpe/van der Heijde score) and bone mineral density.⁹⁴ In osteoarthritis patients, urinary HP and LP levels were increased compared with age-matched controls.⁹⁵ In the same patient population, followed for 1 year, only the cluster of baseline bone metabolism markers (comprising HP, LP, and serum bone sialoprotein)—out of the 14 molecular markers measured—significantly correlated with baseline clinical scores for pain, stiffness, and disease activity.⁹⁶ None of the baseline cartilage or bone metabolism markers correlated with disease progression after 1 year of follow-up.⁹⁶ In these patients, HP that is not derived from bone (extraosseous HP) showed a highly significant correlation with the acute-phase response, suggesting that in osteoarthritis, cartilage degradation is related to the degree of inflammation.⁹⁵

The glycosylated analogue of HP, glucosyl-galactosylpyridinoline (GGHP), is present in human synovial tissue and is released during its degradation *in vitro*. GGHP is virtually absent in bone, whereas low levels have been detected in muscle and liver and intermediate levels have been detected in cartilage. Methodological problems such as the stability of HP during the alkaline hydrolysis that is necessary to liberate glycosylated molecules from tissues have so far prevented solid data on tissue distribution.⁹⁷ Urinary GGHP levels were increased in early RA patients versus controls, and baseline levels correlated with disease progression, albeit weakly.⁷⁵ Pending definite information on its tissue distribution, urinary GGHP might prove to be a marker for synovial tissue degradation.

Overall, collagen cross-links seem useful in measuring bone and cartilage catabolism and contribute to understanding of the pathophysiology of osteoarthritis and RA. In this respect, age-related changes in articular cartilage may significantly affect its susceptibility to proteinase-mediated degradation^{98,99}; this underscores the use of proper age-matched control groups. Results obtained in studies with young animals cannot be extrapolated to the adult human situation.

Collagen Synthesis

In an attempt to repair tissue damage, collagen synthesis is increased in osteoarthritis cartilage, leading to increased tissue levels of the C-terminal propeptide of type II collagen (PIICP, chondrocalcin; also referred to as CPII).¹⁰⁰ The rate of PIICP release is proportional to the rate of current collagen synthesis because the propeptide has a half-life of

approximately 18 hours.¹⁰⁰ Synovial fluid PIICP levels are also increased and correlate with osteoarthritis severity and body mass index.¹⁰¹ PIICP levels were lower in serum of osteoarthritis patients than in that of healthy controls.⁹⁵ Similarly, the serum N-propeptide of collagen type IIA (PIIANP, an alternative splice variant that is expressed in embryonic and osteoarthritic cartilage) is lowered in osteoarthritis serum versus controls. Preliminary studies indicate that the balance between cartilage synthesis (PIIANP) and cartilage degradation (urinary CTx-II) could be used to discriminate between patients with rapid compared with slow progression.⁷⁵ More recently, a competition ELISA was developed for the N-propeptide of the type II collagen isoform that is expressed by mature adult chondrocytes (PIINP).¹⁰² Urine levels of PIINP were twofold higher than plasma levels in persons without radiographic signs of osteoarthritis. In patients with radiographic knee and/or hip osteoarthritis, plasma PIINP levels were fivefold lower than in the reference group without osteoarthritis.¹⁰² A comparable fivefold decrease was observed in RA patients, using a different ELISA.¹⁰³ Absolute values of nanograms PIINP per milliliter plasma were comparable (≈ 18 ng/mL) for both assays and control groups.^{102,103}

In inflamed synovial tissue, the synthesis of type III collagen is upregulated, resulting in the production of its N-terminal propeptide. In osteoarthritis patients and RA patients with knee involvement, serum PIINP levels are increased compared with age-matched controls.^{74,104,105} In RA patients, prednisolone treatment that resulted in clinical improvement also reduced serum PIINP levels by 25% and levels remained suppressed until treatment was withdrawn.¹⁰⁶ Thus far, collagen type III-specific degradation markers have not been described, and because type III collagen has a broad distribution in soft tissues and blood vessels, its potential as a specific biomarker seems limited.

Proteoglycan Markers

The main noncollagenous constituent of articular cartilage is aggrecan, a large proteoglycan composed of a core protein to which glycosaminoglycan chains (e.g., keratan sulfate, chondroitin sulfate) are attached. Researchers have described various assays to measure aggrecan metabolism, but the available information is not always consistent. Depending on the antibodies used, serum keratan sulfate levels were reported to be either increased (antibody 5D4)¹⁰⁷⁻¹⁰⁹ or decreased (antibody AN9P1)¹¹⁰ in osteoarthritis patients compared with controls. Additionally, previous work has suggested that serum 5D4-reactive keratan sulfate levels are either similar¹⁰⁹ or higher in osteoarthritis than in RA.⁸⁸ In one study, the serum keratan sulfate levels (antibody AN9P1) were 30% lower in osteoarthritis patients than in age-matched controls.^{95,96} For RA patients, a negative correlation between serum keratan sulfate levels and inflammation has been found.¹¹¹

The aggrecan epitope 846, which reflects the synthesis of proteoglycans in an attempt to repair, was increased in cartilage of osteoarthritis patients,¹¹² and synovial fluid levels correlated with other markers such as cartilage oligomeric matrix protein (COMP), PIICP, tissue inhibitor of metalloproteinases 1 (TIMP-1), MMP-1, and MMP-3, as well as with the degree of radiologic damage.¹¹³ The epitope

846 levels in serum were lower, however, in osteoarthritis patients than in healthy controls^{96,114} and RA patients.^{88,96} In the RA patients, elevated levels of epitope 846 could predict a benign course of the disease.¹¹⁵ Taken together, none of the aggrecan-derived markers has shown sufficient power to discriminate between patients and controls or to provide consistent information that can be used in clinical studies. This effect may be partly caused by diurnal variation of these biomarkers, which may obscure relevant differences between study groups, especially when serum or urine sampling is not standardized.¹¹⁶ Similarly, increased motility of patients after initiation of successful treatment may affect circulating proteoglycan biomarker levels.

The identification of two members of the ADAM-TS family of proteases (ADAM-TS4 and ADAM-TS5) as aggrecanases¹¹⁷ supplied new tools to develop aggrecan-based markers for cartilage destruction. Antibodies directed at aggrecanase and MMP-generated neoepitopes in aggrecan core protein have been produced and applied in a variety of in vitro studies aimed at unraveling mechanisms of cartilage destruction in osteoarthritis. In synovial fluid from patients with a variety of joint diseases, MMP and aggrecanase-released aggrecan fragments have been detected.¹¹⁸⁻¹²⁰ These studies have also shown that these two groups of proteases may have distinct roles in articular cartilage catabolism.¹²¹

Hyaluronan

The glucuronic acid chain hyaluronan (hyaluronic acid) is a constituent of cartilage and synovium and is synthesized by many cell types. It functions as the anchor for proteoglycans such as aggrecan, allowing the formation of the large aggregates that are responsible for the resilience of cartilage. In the synovial membrane, hyaluronan is synthesized by synovial fibroblasts and secreted into the synovial fluid to provide lubrication of the joint and to facilitate joint movement. Synovial fluid hyaluronan levels are decreased in osteoarthritis patients¹²² and may partly explain impaired joint function and pain. This provides the rationale for visco-supplementation therapy in osteoarthritis patients, consisting of intra-articular injections with hyaluronan derivatives.

Elevated blood hyaluronan levels have been reported for osteoarthritis patients and RA patients. In RA, some studies failed to show a relationship between plasma hyaluronan levels and measures of disease activity,¹²³ whereas others showed significant correlations between serum hyaluronan levels and a variety of measures of inflammation and destruction (e.g., CRP, ESR, Ritchie index, radiologic damage).¹²⁴ In osteoarthritis patients, elevated serum hyaluronan levels correlated weakly with the degree of cartilage degeneration.¹²³ In addition, baseline hyaluronan levels could predict progression of osteoarthritis^{77,125} and serum levels were shown to increase with disease severity.¹²⁶ These results suggest that an increase in circulating systemic hyaluronan levels could reflect synovial inflammation rather than cartilage destruction, prompting care in use of hyaluronan as a joint destruction marker. Also, the observation that diet and increased physical activity can influence its serum levels should be considered when using hyaluronan as a biomarker in joint diseases.^{116,127}

Cartilage Oligomeric Matrix Protein

Since its discovery in the early 1990s, COMP has received much attention as a putative cartilage destruction marker. Although its exact function is unclear, COMP has been implicated in collagen fibrillogenesis. Increased COMP levels have been detected in the synovial fluid of osteoarthritis patients.¹²⁸ In addition, COMP levels are increased in the serum of osteoarthritis patients compared with healthy controls^{74,129} and are associated with progression of radiographic signs of osteoarthritis.¹³⁰ In osteoarthritis patients, the serum COMP levels were even higher than in RA patients.¹³¹ In early RA patients, increased serum COMP levels were identified as a strong predictor of early large-joint destruction.¹³²⁻¹³⁴ These data generated interest in the use of measurement of COMP levels as a selective cartilage destruction marker.

The expression of COMP in joint tissues other than cartilage including synovium, tendons, ligaments, and menisci raised concerns about its tissue specificity. High expression of COMP messenger RNA (mRNA) has been shown in murine osteoarthritis, indicating that synovial fluid COMP levels may reflect not only tissue degradation, but also the rate of new synthesis.¹³⁵ The concerns about the use of COMP measurement as a specific cartilage degradation marker are fueled further by a study showing that the extent of synovial inflammation is one of the factors determining the serum COMP.¹³⁶ In concordance, in early RA a positive correlation was found between serum COMP and the inflammatory marker CRP. Circulating COMP levels in this study were statistically higher in patients showing bone erosions on magnetic resonance imaging (MRI) than those without bone erosions.¹³⁷ Other investigators did not observe a relationship between markers of inflammation and serum COMP levels (using a polyclonal antiserum recognizing all COMP forms) in RA patients.¹³⁸ In this same study, COMP levels did not have any prognostic value with respect to progression of joint damage.¹³⁸ Similar to the CTx and ICTP assays for collagen degradation, the use of antibodies or antiserum recognizing different epitopes within (fragments of) the COMP molecule might explain the apparent inconsistent results in the literature.¹³⁹

Metalloproteinases

In addition to cartilage breakdown products, metalloproteinases (MMPs and aggrecanases) and their endogenous inhibitors (TIMPs) that are involved in the pathologic degradation of joint tissues could serve as useful markers. Data on MMP levels as a predictor for the progression of joint erosion in early RA are rapidly accumulating. Serum and synovial fluid MMP-3 (stromelysin) levels are increased in RA patients compared with controls.^{75,140} MMP-3 levels correlate with inflammation markers and disease activity in patients with untreated active RA¹⁴¹ and in early RA patients who received nonsteroidal anti-inflammatory drugs only.^{138,140} In these studies, serum MMP-3 levels were not related to radiographic progression.¹³⁸ Another study revealed an association between serum proMMP-3 concentrations at disease onset and progression of joint destruction, which was independent of known risk factors such as the presence of the shared epitope and serum levels of

rheumatoid factor and CRP.¹⁴² Serum MMP-3 also correlated significantly with radiographic progression at entry and longitudinally in a study with early RA patients.¹⁴³ In addition, it was demonstrated in a prospective study that increased serum MMP-3 is a predictive marker for the progression in disability.¹⁴⁴ Several investigators showed that MMP-3 levels respond to therapeutic intervention with disease-modifying antirheumatic drugs (DMARDs), resulting in decreased MMP-3 level, which is associated with clinical improvement.^{27,30,143,145-147} Furthermore, baseline serum MMP-3 levels contribute to reaching normal physical function after 2 years of infliximab (anti-TNF) treatment.¹⁴⁸

MMP-1 (collagenase) levels have also been shown to indicate joint erosion independent of inflammation. In early RA patients, there was a positive correlation between the area under the curve measurements of MMP-1 serum levels (but not the area under the curve of CRP levels) and the number of new joint erosions after 18 months of follow-up.¹⁴⁰ Arthritic patients treated with anti-TNF antibodies (infliximab) for 14 weeks did not show reduced MMP-2 and MMP-9 levels (assessed by zymography, which does not reliably detect the other MMPs) despite clear clinical improvement.¹⁴⁹ These data suggest that MMP levels, although they may be correlated with parameters of inflammation, do not reflect exactly the same pathways as do acute-phase reactants and could provide valuable additional information on joint destruction in RA.

Extrapolated to osteoarthritis, in which secondary inflammation is usually mild, these data suggest that MMP levels may provide valuable predictive markers. In a cross-sectional study in osteoarthritis patients, MMP-3 serum levels were similar, however, to levels in healthy controls.¹⁵⁰ In a subset (120 patients) of 431 patients participating in a randomized, placebo-controlled trial evaluating the effects of doxycycline treatment on unilateral knee osteoarthritis, baseline plasma MMP-3 levels predicted joint space narrowing.¹⁵¹ In another study, the serum levels of TIMP-1 did not differ significantly between patients with unilateral or bilateral hip osteoarthritis and healthy controls.¹⁵² Within the osteoarthritis group, patients with rapid disease progression (joint space narrowing > 0.6 mm/yr; 1-year follow-up) had significantly lower serum TIMP-1 levels than patients with slow progression (joint space narrowing < 0.6 mm/yr).¹⁵² Apart from these, comprehensive studies for predictive MMP markers in osteoarthritis are not yet available and information about the use of MMP levels in osteoarthritis is still incomplete.

In recent years, more data on the role of aggrecanase in degradation of the major proteoglycan of cartilage (aggrecan) became available. Its pivotal role in tissue destruction is now widely accepted.^{117,153,154} Because of the difficulties in measuring aggrecanase activity in biologic samples, however, their value as a biomarker to monitor joint destruction is not yet fully understood. It is hoped that the more recent development of several aggrecanase assays,^{155,156} especially the immunoaffinity-based liquid chromatography–tandem mass spectrometry (LC-MS/MS) method, which detects cleavage at the ³⁷⁴ARGS site and the ¹⁸²⁰AGEG site,¹⁵⁷ will facilitate its use as a biomarker. The development of pre-clinical models and approaches to develop and evaluate selective aggrecanase inhibitors may contribute to the

development of antiosteoarthritis drugs, which concomitantly are tools to validate the biomarkers.^{93,158,159}

Biologic Markers in Synovial Tissue

Because many inflammatory arthropathies including RA primarily involve the synovial tissue, there has been increased interest in investigations of the pathologic changes in synovial biopsy specimens. This development has been stimulated further by technical advances such as the advent of new methods to obtain synovial tissue specimens from actively inflamed joints and clinically quiescent joints under local anesthesia and because of the development of immunohistologic methods, *in situ* hybridization, quantitative polymerase chain reaction, and microarray technology. Previous work has shown the relationship between the features of rheumatoid synovial tissue on the one hand and arthritis activity¹⁶⁰ and joint destruction¹⁶¹ on the other (see also Chapter 53). The importance of evaluation of synovial tissue samples has been underscored by the observation that clinical signs of arthritis activity are associated with histologic signs of synovitis after treatment of RA patients with the monoclonal antibody alemtuzumab (Campath-1H), despite profound depletion of circulating lymphocytes.¹⁶² Similarly, rituximab treatment leads to a rapid and significant decrease in synovial B cell numbers in only a subset of RA patients, whereas circulating B cells are completely depleted in nearly all patients (Figure 34-3).¹⁶³⁻¹⁶⁵

Several methodological questions needed to be answered before serial synovial biopsy could be used to screen for potentially relevant effects after antirheumatic treatment.¹⁶⁶ It has been shown in cross-sectional studies that biopsy samples can be acquired by blind needle technique and by miniarthroscopy.¹⁶⁷ There are limitations and disadvantages, however, of the use of serial blind needle biopsy in the evaluation of treatment. It is usually restricted to larger joints such as the knee joint; the operator is not able to select the tissue visually, causing potential sampling error;

and it is not always possible to obtain adequate tissue samples. This is especially true when clinically quiescent joints are investigated (e.g., after successful therapy). Comparison of the features of synovial inflammation in biopsy samples from inflamed knee joints and paired inflamed small joints of RA patients revealed that inflammation in one inflamed joint is generally representative of the inflammation in other inflamed joints.¹⁶⁸ It is possible to use serial samples from the same joint, selecting either large or small joints, for the evaluation of antirheumatic therapy. Sampling error can be reduced by selecting at least six biopsy specimens from multiple regions, resulting in variance of less than 10%.^{22,169} When the biopsy samples are taken from an actively inflamed joint, there is on average no clear-cut difference in the features of synovial inflammation or the expression of mediators of inflammation and destruction at the pannus-cartilage junction compared with other regions away from the pannus-cartilage junction.¹⁷⁰⁻¹⁷² Ultrasound-guided biopsy is a newer technique, which can be performed in both small and large joints, bursae, and tendon sheaths under local anaesthesia.¹⁷³ Although this method is appealing, further validation is necessary. A recommendation for standardization of various synovial biopsy techniques to be used in clinical trials has recently been published.¹⁷⁴

An extensive quality control system is required to allow reliable analysis by immunohistochemistry, tissue enzyme-linked immunosorbent assay, quantitative polymerase chain reaction, or microarray analysis.¹⁷⁵ Finally, sophisticated computer-assisted image analysis systems allow reliable and efficient evaluation of the synovial cell infiltrate and the expression of adhesion molecules, cytokines, and MMPs in innovative clinical trials.¹⁷⁶

Using this approach, successful treatment with disease-modifying antirheumatic drugs such as gold,¹⁷⁷ methotrexate,^{22,178,179} and leflunomide¹⁷⁹ was shown to be associated with decreased mononuclear cell infiltration. Similarly, successful treatment of RA patients with infliximab,^{23,180,181} rituximab,^{164,182,183} and abatacept¹⁸⁴ results in reduced

Figure 34-3 Variable tissue response to treatment with the anti-CD20 antibody rituximab in patients with rheumatoid arthritis. Arthroscopic samples were obtained before (**A** and **B**) and 4 weeks after (**C** and **D**) initiation of treatment. Rheumatoid synovial tissue from paired biopsy samples stained for CD22+ B cells. Single staining, peroxidase technique, counterstaining with Mayer's Hämalaunlösung. Original magnification 200 \times .

synovial inflammation. The number of macrophages in the synovium was decreased already 24 to 48 hours after initiation of infliximab treatment.^{24,185} Similarly, high-dose intravenous methylprednisolone reduced expression of TNF in synovial biopsy samples 24 hours after treatment, a result that correlated with a clinical response to, and subsequent relapse after, methylprednisolone therapy.¹⁸⁶

A randomized trial has formally addressed the question of which feature in RA synovial tissue samples could be used as a biomarker for clinical efficacy in relatively small studies of short duration.¹⁸⁷ Patients received either prednisolone according to the COBRA regimen or placebo for 2 weeks. This study identified sublining macrophages as an important immunohistologic biomarker associated with the clinical response to corticosteroids. The utility of macrophages in the synovial sublining as a candidate biomarker across discrete interventions and kinetics has also been observed,¹⁷⁶ with a correlation between the mean change in disease activity score (Δ DAS28) and the mean change in the number of sublining macrophages. When patients from several actively treated studies were grouped, the standardized response mean, a measure of sensitivity to change, was 1.16 for the change in DAS28 and 0.83 for the change in sublining macrophages. For the patients from the placebo groups, the standardized response mean was -0.23 (for DAS28) and 0.30 (for macrophages), consistent with the notion that the biomarker is less susceptible to placebo effects or expectation bias than clinical evaluation, which includes subjective measures of disease activity.^{176,188} In addition to its role as a possible marker of clinical response the change in numbers of sublining macrophages could potentially help to distinguish effective from ineffective treatment. Taken together, these studies suggest that analyses of serial biopsy samples can be used as a screening method to test new drug candidates requiring relatively small numbers of subjects. The absence of changes after treatment would suggest that the therapy is probably not effective. The demonstration of biologic changes at the site of inflammation could provide the rationale for larger, placebo-controlled trials, however. Most of the biopsy studies have been performed in RA patients, but it appears likely that the same approach can be used for the evaluation of novel therapies in patients with other rheumatologic disease such as spondyloarthritis.¹⁸⁹⁻¹⁹²

As an alternative to immunohistologic and in situ hybridization methods, quantitative polymerase chain reaction on small synovial biopsy specimens can be employed to evaluate drug effects in clinical trials.^{166,169} Using this approach, prednisolone was shown to reduce expression of IL-8 and MMP-1 in synovial biopsy specimens of RA patients after 2 weeks of treatment.¹⁹³ Because the biopsy specimens contain various cell types, it is important to realize that a change in gene expression level may also reflect a change in cellular composition of the biopsy, not a change in the expression level within a certain cell type.

Biomarker Panels

Almost none of the markers for osteoarthritis and RA that are currently used can distinguish successfully between patients and controls on an individual basis, although

average marker levels differ among groups. Principal component analysis of 14 biochemical markers revealed that the markers segregate into five clusters: inflammation (IL-6, CRP, TNF receptor I, TNF receptor II, and eosinophil cationic protein); bone (HP, LP, and BSP); cartilage synthesis (CPII, epitope 846, and hyaluronan); cartilage degradation (COMP and keratan sulfate); and transforming growth factor- β 1 (which is independent of all other markers).⁹⁵ The combination of three of the markers (TNF receptor II, COMP, and epitope 846) from the independent clusters inflammation, cartilage degradation, and cartilage synthesis could discriminate correctly between osteoarthritis patients and controls in approximately 90% of the cases.⁹⁵ In a study of 376 patients with hip osteoarthritis, a similar approach resulted in five different clusters with similar makeup: a cartilage and bone cluster (PINP, CTx-I, and CTx-II); a putative synovitis cluster (COMP, PIINP, and HA); a putative systemic inflammation cluster (CRP and YKL-40); and MMP-1 and MMP-3 as two independent factors.¹⁰⁴ Similarly, in RA, a combination of seven clinical scores and molecular markers provided a clinical prediction model that could discriminate, at the first visit, among three forms of arthritis—self-limiting arthritis, persistent nonerosive arthritis, and persistent erosive arthritis.¹⁹⁴ Responsiveness of peripheral blood cells to various stimuli using a 10-cytokine profile resulted in an immunologic signature that performed well in distinguishing early RA patients from controls and also correlated with several markers of disease severity in late RA. In contrast, the same 10-cytokine profile assessed in serum was far less effective in discriminating the groups.¹⁹⁵

Different clusters of biomarkers may relate to osteoarthritis at different joint sites, suggesting that pathophysiologic processes may be different among those sites.⁷⁹ These studies support the notion that panels of biomarkers may provide a valuable additional tool in the monitoring of osteoarthritis patients and RA patients and in helping to understand disease processes.

The progressive destruction of the articular cartilage is considered a major determinant of disability in patients with joint disease. A report showed that the balance between cartilage synthesis and degradation discriminates between osteoarthritis patients with rapid versus slow progression, as assessed by the change in joint space width and arthroscopically scored chondropathy.⁷⁵ These studies support the hypothesis that the “-omics” approaches, combining even more markers than the few used previously, may be successful in the identification of disease-specific fingerprints and may also provide tools to monitor tissue-specific degradation.

“-OMICS” BASE BIOMARKERS

The current technical progress in genomics, transcriptomics, proteomics, and metabolomics, in combination with advanced bioinformatics,¹⁹⁶ makes it possible to analyze numerous markers in one sample, which could be urine, serum, synovial fluid, or (synovial) tissue. The resulting profile combines the levels of a variety of markers to create a “disease fingerprint” that could serve as a powerful marker by itself. In addition to specific markers for early diagnosis,

markers that specifically reflect cartilage degradation are necessary. These technologies can arbitrarily be separated into three primary levels: *genomics*, which deals with variations in DNA composition (e.g., single nucleotide polymorphisms) and expression levels (differences in mRNA levels, also known as transcriptomics); *proteomics*, which analyzes the proteome, or total of proteins in a sample; and *metabolomics*, which focuses on metabolites. Variations on these themes include technologies such as lipidomics (profiling the lipids and free fatty acids in a cell or biologic fluid), degradomics (the study of protein degradation products), and toponomics (the study of the localization of molecules within a cell).

Genomics

Of all the “-omics” technologies, genomics was the first to evolve in the footsteps of the human genome project, and various aspects of genomics approaches to study joint diseases have been extensively reviewed.¹⁹⁷⁻¹⁹⁹ Comparisons in gene expression levels among controls, osteoarthritis, and RA have been made for a variety of tissues such as chondrocytes, blood-derived cells, and synovial tissue. Within a group of RA patients, complementary DNA (cDNA) microarray analysis with a focus on immune-related genes could separate classes of patients with potentially different pathogenicity on the basis of expression of genes involved in the adaptive immune response versus genes involved in tissue remodeling.²⁰⁰ In osteoarthritis, chondrocytes from cartilage have been shown to upregulate the transcription of a variety of inflammatory genes.⁵⁵ In another study, 3543 genes were differentially expressed by blood cells of patients with mild knee osteoarthritis compared with healthy controls.^{201,202} Logistic regression indicated that nine of these genes were discriminatory between subjects with mild osteoarthritis and controls, with a sensitivity of 86% and specificity of 83% in a training set of 78 samples. The optimal biomarker combinations were evaluated using a blind test set (67 subjects), which showed 72% sensitivity and 66% specificity for the diagnosis of osteoarthritis.²⁰¹ These data underscore that the combination of biomarkers (in this case the expression of nine genes) may be useful in differential diagnosis.

Also in other rheumatic diseases, expression profiling has contributed to the understanding of disease pathways. In patients with systemic lupus erythematosus, several studies have shown that interferon-regulated genes are highly upregulated in peripheral blood cells and in kidney glomeruli.²⁰³

One of the ultimate uses of the identification of differentially expressed genes in a disease is illustrated by the antitumor drug trastuzumab (a recombinant monoclonal antibody against the human epidermal growth factor receptor 2 [HER2] protein), which would not have reached the market if not for the accompanying prognostic test.²⁰⁴ Normal cells express low levels of HER2 protein on their plasma membrane. In approximately 25% of breast cancer patients, HER2 is overexpressed, changing the growth control of these cells. The prognostic test measures the expression levels of HER2, assisting in the selection of patients who would benefit from trastuzumab treatment.

Proteomics and Lipidomics

Similar to the genomics revolution, which was partly driven by technology that allowed the production of gene-chip and high-throughput DNA sequencing methods, the proteomics field was boosted by the development of better two-dimensional electrophoresis technologies, protein and antibody arrays, and the rapid improvements in the area of mass spectroscopy, all of which facilitated the reproducible analysis of a panel of proteins within a sample.^{205,206} Two-dimensional gel electrophoresis has been used to identify proteins secreted into the culture medium of normal and osteoarthritic cartilage samples²⁰⁷ but also to analyze the protein composition of the mitochondria of healthy human chondrocytes.^{208,209} Using surface-enhanced laser desorption/ionization time-of-flight mass spectroscopy, 103 serum samples of RA patients; osteoarthritis patients; patients with non-RA inflammatory conditions (psoriatic arthritis, asthma, Crohn's disease); and controls were analyzed. This approach yielded several signals in the mass spectrum that contributed to the separation between RA patients and controls.²¹⁰

A different approach was taken by Xiang and co-workers,²¹¹ who first separated human chondrocyte proteins by two-dimensional electrophoresis, then blotted the proteins to a membrane, and finally incubated these membranes with serum of osteoarthritis patients, RA patients, and controls to identify which chondrocyte-derived autoantigens are present in these patients. This approach yielded triosephosphate isomerase as a potential osteoarthritis-specific biomarker. Using a protein microarray platform that simultaneously evaluates the presence and abundance of 169 proteins relevant to inflammation, cell growth, activation, and metabolism, 16 serum proteins were found different between OA cases compared with controls.²¹² Yet another approach focuses on the panels of autoantibodies present in patients with various autoimmune diseases to act as biomarkers.²¹³ Using an array of 30 antigens known to be expressed in the glomeruli, researchers studied the clusters of autoantibodies that occur in the serum of lupus patients and found they were related to the patients' disease activity.^{214,215} All biomarkers that are identified by the previously described examples naturally need further validation to establish their true usefulness for diagnostic, prognostic, or disease-monitoring application in patients with joint disease.

From recent advances in analytic methods to simultaneously analyze multiple lipid species emerges the field of lipidomics, which can be divided into two biochemical areas of equal significance: membrane functional-lipidomics and mediator functional-lipidomics.^{216,217} Osteoarthritis has long been considered a disease in which irreversible degradation of articular cartilage was the pivotal pathophysiologic process. Recent studies that indicate the development of osteoarthritis may be related to the coexistence of disordered glucose and lipid metabolism have triggered the evaluation of the lipidome in osteoarthritis patients. Using ultra-performance liquid chromatography coupled to time-of-flight mass spectroscopy (UPLC-ToF-MS), clear differences in serum lipid composition were observed between subjects with no, mild, or moderate osteoarthritis.²¹⁸

Metabolomics

Biologic fluids such as urine, blood, and synovial fluid contain numerous metabolites that may provide valuable information on the metabolism of an organism and about its health status. Metabolic profiling, also referred to as *metabolomics*, *metabonomics*, or related terms, is defined as the quantitative and qualitative analysis of the whole complement of small molecules in a sample (e.g., cell, tissue, body fluids).²¹⁹ The technology has emerged from approaches used to profile body fluids that were developed many decades ago for the study of inborn errors of metabolism and the effects of nutrition. A wide array of analytic methods is used to analyze the various metabolites. Gas chromatography–mass spectroscopy and nuclear magnetic resonance (NMR) can be employed for a global insight into a broad range of metabolites such as (phosphorylated) sugars, amino acids, fatty acids, nucleobases and nucleosides, amines, higher alcohols, and bile acids. Liquid chromatography–mass spectroscopy methods can be used to not only zoom in on free fatty acids and lipids but also analyze amino acids, peptides, sugars, aminosugars, hormones, and steroids. All of these analytic measures need to be combined with data preprocessing to obtain clean data. This is necessary to analyze these large metabolite profiles reliably and to relate relevant changes in metabolites to biologic processes, using multivariate statistics.

The application of metabolomics in the area of joint diseases is relatively recent. ¹H-NMR (500 MHz) has been used to compare the effects of unilateral knee joint denervation on the biochemical profiles of synovial fluid in a bilateral canine anterior cruciate ligament transection model of osteoarthritis. Increases in glycerol, hydroxybutyrate, glutamine/glutamate, creatinine/creatine, acetate, and *N*-acetyl-glycoprotein concentrations were observed in synovial fluids from denervated osteoarthritis knees compared with normally innervated osteoarthritis knees.²²⁰ These metabolite profiles of denervated osteoarthritis knees support the idea of neurogenic acceleration of osteoarthritis in that the observed differences in metabolite concentrations found in the denervated knee fluids seem to correlate with metabolic changes resulting from aggravation of the osteoarthritis process caused by joint denervation.²²¹ Using ¹H-NMR (300 MHz) and multivariate data analysis, a metabolite profile was detected, which was strongly associated with osteoarthritis in 10- and 12-month-old Hartley guinea pigs that spontaneously develop osteoarthritis.²²² ¹H-NMR also revealed a urinary metabolite profile that could distinguish osteoarthritis patients from healthy individuals.²²³ The human urine profile largely resembles the Dunkin Hartley guinea pig profile; the presence of hydroxybutyrate, pyruvate, creatine/creatinine, and glycerol in the metabolite profile could point to an enhanced use of fat and altered energy use, consistent with the canine synovial fluid composition.^{220,221,223}

SYSTEMS BIOLOGY

Although each is already tremendously powerful on its own, the combination of genomics (transcriptomics), proteomics, and metabolomics theoretically could deliver a full picture of a living system (cell, organ, or organism). Such a systems

biology approach²²⁴ would provide insight into which disturbances of a healthy system cause it to shift toward a pathologic phenotype, which mechanisms are employed by the organism to maintain its equilibrium, and which factors indicate a point of no return, followed by failure of the intrinsic balancing mechanisms and disease initiation. As such, a systems biology approach would help to identify the most promising molecules that describe this shift and can act as biomarkers, while concomitantly key molecules can be detected that, when normalized, could rebalance the system, acting as therapeutic targets. The first steps in this area are being made for RA,²²⁵ but steps for osteoarthritis projects also have been initiated.

BIOMARKER VALIDATION AND APPLICATION

Following or parallel to the crucial investigations to identify relevant biomarkers for disease, validation studies need to be performed that focus on analytic aspects and clinical validity: Does the biomarker reflect the disease process, and how does it change with endogenous or drug-induced changes in pathophysiologic processes? The actual application of such biomarkers in preclinical or clinical studies requires an in-depth analytic validation. The obvious reason for this is that to draw conclusions on the basis of biomarker data, it is essential to be able to trust that a measured value is reliable and reproducible. The HELIX-II example (see earlier) illustrates the importance of characterizing the analyte of interest and ensuring that the chosen assay detects that specific analyte.⁹² Some of the essential steps in biomarker validation are described next. Details on validation procedures and requirements can be found elsewhere (www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/UCM267449.pdf).²²⁶ The fundamental technical parameters to show that a given biomarker can be quantitatively measured in a given biologic matrix (e.g., serum, urine, synovial fluid, saliva) include the following:

1. Accuracy—how close is the mean measured concentration of at least five replicates to the true value of the analyte?
2. Precision—what is the variation between individual measurements of one sample? Typically, at each test concentration, the precision should not exceed the 15% of the coefficient of variation.
3. Selectivity or specificity—how well does the analytic method distinguish between the analyte of interest and other components of the samples?
4. Sensitivity—what is the smallest amount (or the largest amount) of analyte that can be reliably detected?
5. Reproducibility—how well can the measurements be repeated on a different day, by different operators, or by using different equipment and still result in the same measured values?
6. Stability—how stable is the analyte of interest in a certain matrix, tube, or storage condition? This also includes studies of the stability of the analyte on repeated freeze-thaw cycles and short-term and long-term storage at various temperatures.

Other factors that are important in validating biomarker assays are the availability of references or calibrators that are used as external standards to quantify the results. In addition, the development of standard operating procedures and documentation is essential for optimal assay performance.

Many biomarkers (e.g., urinary CTx-II) are measured in body fluids such as urine, serum, or plasma and related to disease end points in one joint (e.g., radiologic knee osteoarthritis), thereby ignoring the contribution of other joints and tissues to the systemic biomarker levels. This commonly used approach is one of the underlying reasons for the inconsistent performance of various osteoarthritis biomarkers.²²⁷ Proper biomarker validation would include relating the systemic biomarker level to whole body burden of disease, which is hampered by the inability to fully phenotype the burden of osteoarthritis in a patient. Osteoarthritis presence and severity in single or sometimes multiple joints are currently documented by radiographs and/or magnetic resonance imaging. Using this approach on a routine basis for whole body burden of disease is impractical due to radiation exposure, time, and cost. Therefore proper biomarker validation would have the concomitant advantage of providing a cost-effective alternative to whole body imaging. An initial study suggests that indeed systemic joint tissue concentrations of several biomarkers can be quantitative indicators of specific subspecies of osteoarthritis and of total body burden of disease.⁶

The applicability of biomarkers does require more than validation. Sharing reagents, standards, and procedures among laboratories enables the comparison of study results and therefore the advancement of the field. The BIPEDS classification (which stands for Burden of Disease, Investigative, Prognostic, Efficacy of Intervention, Diagnosis of Disease, and Safety of Intervention) for osteoarthritis biomarkers was developed by the National Institutes of Health-funded osteoarthritis Biomarkers Network to improve the ability to develop and analyze osteoarthritis biomarkers, as well as to communicate these advances within a common framework.^{2,6} A review of the status of commercially available biochemical markers for primary knee and/or hip osteoarthritis according to the BIPED classification revealed an uneven distribution of scores on biochemical marker performance, and heterogeneity among the 84 evaluated publications complicated direct comparison of individual biochemical markers.²²⁷ This underscores the need for international standardization of future investigations to obtain more high-quality, homogeneous data on the full spectrum of biochemical markers.

In the field of RA the Outcome Measures in Rheumatology (OMERACT) initiative is an informal international network that strives to improve end point outcome measurement through a data-driven, interactive consensus process. The initiative has established an OMERACT filter to assess whether a measure is applicable. The filter can be summarized in three words: (1) truth (does it measure what it intends to measure?), (2) discrimination (does the measure discriminate between situations of interest?), and (3) feasibility (can the measure be applied easily, given constraints of time, money, and interpretability?). At the OMERACT 8 meeting a draft set of criteria for the validation of soluble biomarkers reflecting damage end points was proposed, and

the Soluble Biomarker Group revised it at OMERACT 9.^{228,229} The set of criteria (OMERACT 9 v2 criteria) focuses on the performance characteristics of biomarker assays, the importance of addressing potential confounders, and the requirement for clinical validation studies. Well-designed prospective studies adhering to the guidelines formulated by the Soluble Biomarker group should be performed to establish if a (panel) of soluble biomarkers can reliably reflect the disease processes in RA and replace the measurement of joint destruction in RA.²³⁰

Given the current developments in the field of RA with recommendations to treat early in the disease with DMARDs for the best outcome on disease progression, it becomes increasingly important to identify RA patients at an early stage. To this end, experts developed a new set of criteria for classification that consists of clinical and inflammatory markers (i.e., CRP, RF, ACPA, and ESR) and has to prove its value in future studies.²³¹⁻²³³ On the other hand, a prediction rule has been developed. It includes several of the classical soluble biomarkers (CRP, RF, and ACPA) to classify the patients and has subsequently been validated in several other studies.²³⁴⁻²³⁷

Future challenge also lies in the prediction of response to a certain treatment. For instance, about one third of the RA patients does not respond to anti-TNF treatment. Patients would greatly benefit from developments that predict their responsiveness to a treatment. It would not only avoid exposing patients to potential risks known to come with the use of certain biologics, but also positively influence the economic burden of treating RA patients. In literature, the focus has predominantly been on predicting the response to anti-TNF therapies because this therapy is widely applied once the response to methotrexate (first line of treatment) is not sufficient. Several approaches have been used by investigators to predict the response to anti-TNF therapies including the use of single biomarkers, panels of biomarkers, expression profiles, and the presence of lymphocyte aggregates in the synovium.²³⁸⁻²⁴³ All of these prediction models should be validated in independent large cohort studies to confirm their value for distinguishing responders from nonresponders to anti-TNF therapies.

CONCLUSION

Over the years, many reports have been published that employ molecular markers in body fluids to assess inflammation and tissue destruction in joint diseases. Starting from single markers with limited tissue or disease specificity, panels of biomarkers are increasingly used and these become more and more tissue specific. The novel markers include collagen-based markers (telopeptides, neoepitopes, and cross-links), COMP, and MMPs, which are often included in clinical trials. Apart from well-known markers such as CRP, ESR, rheumatoid factor, anticitrullinated protein/peptide antibodies, and a few other autoantibodies, none of the markers has made it to the clinic for routine evaluation of patient disease status. The requirements for such a clinically useful marker are high because it should be superior to existing markers in being able to predict disease progression or monitor therapy efficacy in individual patients. In this respect, biomarkers for osteoarthritis provide the greatest challenge: Joint destruction often proceeds without signs of

inflammation. Validation of osteoarthritis biomarkers is hampered by the absence of a generally accepted, effective treatment for the disease. In early RA patients, suppression of inflammation often, although not always, coincides with decreased joint destruction, and monitoring inflammation may fulfill its role as surrogate destruction marker. In later stages of the disease, when inflammation and destruction seem more uncoupled,²⁴⁴ specific destruction markers also are necessary for RA patients. In general, the combination of multiple markers holds most promise to meet these needs to increase disease specificity or tissue specificity, or both, and to reduce the extensive overlap in marker levels that exists between patients and controls.

Analysis of molecular markers in synovial tissue is increasingly used, especially in clinical trials on targeted therapies. Tissue specificity is not a problem, and examination of serial biopsy samples may be used to monitor the response in individual patients and screen for interesting biologic effects at the site of inflammation. This approach is generally well tolerated by patients, but it requires a more demanding setup. It can be anticipated that future development will include the use of more extensive markers of joint degradation—in addition to the available markers of inflammation—and the use of panels of biomarkers in synovial tissue samples.

As illustrated by studies described in this chapter, many investigators measure different sets of biomarkers and may use different definitions of disease (or progression or both). In addition, common terminology to describe a biomarker is lacking and investigators may have a historical bias in favor of (or against) certain biomarkers. In combination, these issues may slow down the urgently needed progress in the development of clinically applicable biomarkers for joint diseases. To solve this, further collaboration between researchers of various disciplines and the execution of large, unbiased studies incorporating a wide panel of available (or newly developed) biomarkers and complementary methods including imaging and patient assessments are necessary.²⁴⁵

KEY POINTS

Some occupational and recreational activities have been linked with musculoskeletal syndromes or disorders. These include certain syndromes manifested by neck pain; shoulder, elbow, hand, or wrist pain or tendinitis; carpal tunnel syndrome; and hand-arm vibration syndrome.

The concepts of so-called cumulative trauma disorders and repetitive strain disorders, though intuitive, are poorly supported by the literature. Causal relationships between most occupations or activities and these “syndromes” have not been well established.

Some activities and mechanical stresses have been associated with osteoarthritis at certain sites—for example, the hips of farmers, the knees of workers whose jobs involve frequent knee bending, and the hands of workers doing repetitive tasks with their hands. Seamstresses, diamond workers, and textile workers are among the latter.

Certain rheumatic disorders have been related to environmental or occupational risks such as Raynaud’s phenomenon with vibration and polyvinyl chloride; autoimmune disease with schoolteachers; scleroderma with chlorinated hydrocarbons, organic solvents, and silica; scleroderma-like syndromes with rapeseed oil and L-tryptophan; lupus syndromes with canavanine, hydrazine, mercury, pesticides, silica, mercury, paints, dyes, nail polish, and solvents; vasculitis with farming, silica, solvents, and allergies; granulomatous vasculitis with mercury and lead; lupus, scleroderma, and Paget’s disease with pet ownership; rheumatoid arthritis with silica (Caplan’s syndrome); and saturnine gout with lead exposure.

Putting a normal joint through its physiologic range of motion is not necessarily harmful for an otherwise healthy individual; however, if the joint, motion, stress, or biomechanics are not normal, there may be a risk of joint harm.

Most normal individuals comfortably engaging in reasonable recreational activities can do so without evidence of lasting soft tissue or articular damage; runners have been best studied. Conversely, individuals who exercise with pain, effusions, underlying joint abnormalities (e.g., ligamentous or meniscal damage), or abnormal or unusual biomechanics or as professional or elite athletes (e.g., boxers, American football or soccer players) seem to be at increased risk of joint injury.

Performing artists, vocalists, dancers, and musicians have a risk of soft tissue and joint injury analogous to that of athletes.

Occupational and Recreational Musculoskeletal Disorders

KARINA D. TORRALBA •
RICHARD S. PANUSH

“The diseases of persons incident to this craft arise from three causes: first constant sitting, second the perpetual motion of the hand in the same manner, and thirdly the attention and application of the mind. ... Constant writing also considerably fatigues the hand and whole arm on account of the continual and almost tense tension of the muscles and tendons. I knew a man who, by perpetual writing, began first to complain of an excessive weariness of his whole right arm, which could be removed by no medicines, and which was at last succeeded by a perfect palsy of the whole arm.”

—Ramazzini, 1713¹

“When job demands ... repeatedly exceed the biomechanical capacity of the worker, the activities become trauma-inducing. Hence, traumatogens are workplace sources of biomechanical strain that contribute to the onset of injuries affecting the musculoskeletal system.”²

This chapter discusses the possible association of certain occupational and recreational activities with musculoskeletal disorders. It has been conventional wisdom that “wear and tear” from at least some activities leads to reversible or irreversible damage to the musculoskeletal system.²⁻⁵ Despite the apparent logic that work or recreational activities might cause rheumatic and musculoskeletal disorders or soft tissue syndromes, this putative association is controversial and perhaps seriously flawed. There are confounding aspects to many of the available data including imprecise diagnostic labels, subjectivity of complaints, anecdotal and survey data, inadequate controls, differing definitions of disease and disability, limited duration of follow-up observations, inadequate epidemiology, inferential observations, difficulty quantifying activities and defining health effects, assumptions of the validity of claims data, variable quality of reported observations, psychologic factors influencing symptoms, and conflicting data.

OCCUPATION-RELATED MUSCULOSKELETAL DISORDERS

Many presumptive work-related musculoskeletal disorders have been described and are summarized in [Table 35-1](#).¹⁻¹¹ These have been reported as sprains, strains, inflammations, dislocations, and irritations. Work-related musculoskeletal injuries comprise at least 50% of nonfatal injury cases resulting in days away from work.¹² The cost of work-related disability from musculoskeletal disorders has been equivalent to approximately 1% of the United States’ gross national product, making these entities of considerable

societal interest.¹³ Industries with the highest rates of musculoskeletal disorders include meatpacking, knit-underwear manufacture, motor vehicle manufacture, poultry processing, mail and message distribution, health assessment and treatment, construction, butchery, food processing, machine operation, dental hygiene, data entry, hand grinding and polishing, carpentry, industrial truck and tractor operation, nursing assistance, and housecleaning. There have been imprecise associations between work-related musculoskeletal syndromes and age, gender, fitness, and weight.^{6,10,11}

A number of work-related regional musculoskeletal syndromes have been described. These include disorders of the neck, shoulder, elbow, hand and wrist, lower back, and lower extremities¹⁰ (Table 35-2); some of these are discussed in greater detail in other chapters. Neck musculoskeletal disorders were associated with repetition, forceful exertion, and constrained or static postures. Shoulder musculoskeletal disorders occur with work at or above shoulder height, lifting of heavy loads, static postures, hand-arm vibration, and repetitive motion. For elbow epicondylitis, risk factors were overexertion of finger and wrist extensors with the elbow in extension, as well as posture. Hand-wrist tendinitis and work-related carpal tunnel syndrome were noted with repetitive work, forceful activities, flexed wrists, and duration of continual effort.^{1,10} Hand-arm vibration syndrome (Raynaud-like phenomenon)¹⁴ has been linked to the intensity and duration of vibrating exposure. Work-related lower back disorders are associated with repetition, the weight of objects lifted, twisting, and poor biomechanics of

lifting.^{14,15} Other risk factors for work-related musculoskeletal disorders involving the back included awkward posture, high static muscle load, high-force exertion at the hands and wrists, sudden applications of force, work with short cycle times, little task variety, frequent tight deadlines, inadequate rest or recovery periods, high cognitive demands, little control over work, cold work environment, localized mechanical stresses to tissues, and poor spinal support.¹

The development of recommended treatment methods (rehabilitation) for these so-called occupational musculoskeletal disorders has included collaboration by workers, employers, insurers, and health professionals. The process has been divided into three phases: protection from and resolution of symptoms, restoration of strength and dynamic stability, and return to work. This process included symptomatic therapies, physical therapy, and ergonomic evaluation.⁷ Prognosis for these maladies has not been well studied or defined.⁸

Until recently, the prevailing view was that many musculoskeletal disorders were consistently and predictably work related. That understanding has now come under considerable scrutiny and criticism.^{2,16–25} Despite the quantity of published information (see Table 35-2), the previously cited literature about occupational musculoskeletal disorders is now considered flawed; its quality was uneven and perhaps poor in some instances. Definitions of musculoskeletal disorders were imprecise; diagnoses, by rheumatologic standards, were infrequent; studies were usually not prospective, and there were selection biases; psychologic influences and secondary gain were often ignored; questionnaires were often used without validation of subjective complaints; and quantification of putative causative factors was difficult. Indeed, a review of this literature concluded that none of the published studies satisfactorily established a causal relationship between work and distinct medical entities.²¹ In fact, certain experiences argued powerfully against the notion of work-related musculoskeletal disorders. In Lithuania, for example, where insurance was limited and disability was not a societal expectation or entitlement, “whiplash” from auto accidents did not exist.²⁰ In Australia, when legislation for compensability was made more stringent, an epidemic of whiplash and repetitive-strain injuries abated.^{22,24} In the United States, too, expressed symptoms correlated closely with the likelihood of obtaining compensation.²⁶ In other cases, ergonomic interventions had no effect on alleged work-related symptoms and close analysis of epidemics of work-related musculoskeletal disorders revealed serious inconsistencies.¹⁸ These concerns led the American Society for Surgery of the Hand to editorialize that “the current medical literature does not provide the information necessary to establish a causal relationship between specific work activities and the development of well-recognized disease entities. Until scientifically valid studies are conducted, the society urges the government to exercise restraint in considering regulations designed to reduce the incidence of these conditions because premature regulations could have far-reaching legal and economic effects, as well as an adverse impact on the care of workers.”¹⁹

One review summarized that “most believe scientific data are insufficient to establish a definite causal relationship of these so-called cumulative trauma disorders to the worker’s

Table 35-2 Selected Literature Describing Regional Occupation-Related Musculoskeletal Syndromes

Syndrome	No. of Epidemiologic Studies	Odds Ratio/Relative Risk
Neck pain	26	0.7–6.9

Elbow tendinitis	14	0.7–5.5
Hand-wrist tendinitis	16	0.6–31.7
Carpal tunnel syndrome	22	1–34
Hand-arm vibration syndrome	8	0.5–41

occupation, and many believe the issue has become a sociopolitical problem.”⁹ Hadler^{2,16-18} has written particularly forcefully that popular notions about work-related musculoskeletal disorders have been based on inadequate science. Others, too, have expressed serious reservations about the cumulative trauma disorder hypothesis including the Industrial Injuries Committee of the American Society for Surgery of the Hand, the Working Group of the British Orthopaedic Association, and the World Health Organization.^{2,16-18,21,23}

An appreciation of the importance of psychosocial factors influencing work disability has emerged. These factors included lack of job control, fear of layoff, monotony, job dissatisfaction, unsatisfactory performance appraisals, distress and unhappiness with co-workers or supervisors, repetitive tasks, duration of work day, poor quality of sleep, perceptions of air quality and ergonomics, poor coping abilities, divorce, low income, less education, poor social support, presence of chronic disease, poor sleep quality, self-rated perception of poor air quality, and poor office ergonomics.^{2,16-30} This is reminiscent of the story of silicone breast implants and their presumed association with rheumatic disease. In this instance—as seems to be the case with work-related musculoskeletal disorders—there was a coalescence of naïvely simplistic assumptions, untested hypotheses, confusion between the repetition of hypotheses and their scientific validation, media exaggeration, and public advocacy intertwined with politics and governmental regulatory agencies, dollar jackpots, litigation, and inadequate science. All these elements confounded and perverted the silicone breast implant story^{31,32} and may have confused the interpretation of evidence-based work-related musculoskeletal disorders as well. More good-quality, standardized investigation is necessary to learn about work-related musculoskeletal disorders and to clearly identify the circumstances in which they occur. Work-related musculoskeletal disorders probably exist, but they are likely to be less pervasive and less noxious than originally thought.

OCCUPATION-RELATED RHEUMATIC DISEASES

Work-related rheumatic diseases have not been consistently well studied, but associations between occupations and well-defined rheumatic disorders are clearer than those involving musculoskeletal disorders. This topic also recapitulates the simplistic notion that joints deteriorate with use. However, this perception is neither necessarily logical nor correct.

Osteoarthritis

Is osteoarthritis (OA) caused, at least in part, by mechanical stress? One analytic approach to determining a possible relationship between activity and joint disease is to consider the epidemiologic evidence that degenerative arthritis may follow repetitive trauma. Most discussions of the pathogenesis of OA include a role for “stress.”³³⁻⁵⁰ Several studies have suggested an increased prevalence of OA of the elbows, knees, and spine in miners³⁸⁻⁴⁰; of the knees in floor layers and in other occupations requiring kneeling; of the knees

in shipyard workers and a variety of occupations involving knee bending; of the shoulders, elbows, wrists, and metacarpophalangeal joints in pneumatic drill operators⁴²; of the intervertebral disks, distal interphalangeal joints, elbows, and knees in dockworkers³⁹; of the hands in cotton workers,⁴³ diamond cutters,^{38,44} seamstresses,⁴⁴ and textile workers^{45,46}; of the knees and hips in farmers; and of the spine in foundry workers⁴⁷ (Table 35-3). Population studies have noted increased hip OA in farmers, firefighters, mill workers, dockworkers, female mail carriers, unskilled manual laborers, fishermen, and miners and have reported increased knee OA in farmers, firefighters, construction workers, house and hotel cleaners, craftspeople, laborers, and service workers.⁴⁷⁻⁵⁰ Activities leading to an increased risk for premature OA involve power gripping, carrying, lifting, increased physical loading, increased static loading, kneeling, walking, squatting, and bending.⁴⁷⁻⁵⁰ Recent studies and systematic reviews have confirmed/adduced that heavy lifting and crawling but not climbing were associated with knee and hip OA; individual studies were variable, often small, and with interpretive limitations.⁵¹⁻⁵⁴ The effect of body mass index in work-related osteoarthritis appeared to predispose toward the development of knee osteoarthritis, with primarily valgus malalignment.⁵⁵⁻⁵⁷

Studies of skeletons of several populations have suggested that age at onset, frequency, and location of osteoarthritic changes were directly related to the nature and degree of physical activities.⁵⁸ However, not all these studies adhered to contemporary standards, nor have they been confirmed. One report, for example, failed to find an increased incidence of OA in pneumatic drill users and criticized inadequate sample sizes, lack of statistical analyses, and omission of appropriate control populations in previous reports.⁴⁰ The investigators further commented that earlier work was “frequently misinterpreted” and that their studies suggested that “impact, without injury or preceding abnormality of either joint contour or ligaments, is unlikely to produce osteoarthritis.”⁴²

Do epidemiologic studies of OA implicate physical or mechanical factors related to disease predisposition or development? The first national Health and Nutrition Examination Survey of 1971 to 1975 (HANES I) and the Framingham studies explored cross-sectional associations between radiographic OA of the knee and possible risk factors.⁴⁷⁻⁶⁵ Strong associations were noted between knee OA and obesity and those occupations involving the stress of knee bending, but not all habitual physical activities and leisure-time physical activities (running, walking, team sports, racquet sports, and others) were linked with knee OA.^{33-35,66-68} (See Chapter 98 for more information concerning the pathogenesis of OA.)

Other Occupational Rheumatologic Disorders

Certain rheumatic diseases other than repetitive strain or cumulative trauma disorders have been associated with occupational risks. These included reports of reflex sympathetic dystrophy after trauma; Raynaud’s phenomenon with vibration or exposure to chemicals (polyvinyl chloride); autoimmune disease from teaching school, farming and occupations with exposure to animals and pesticides, mining, textile machine and decorating operations^{50,69};

DIP, distal interphalangeal; MCP, metacarpophalangeal; OA, osteoarthritis.

scleroderma from chemicals, silica, solvents, and use of vibrating tools⁷⁰⁻⁷⁴; scleroderma-like syndromes from rapeseed oil and L-tryptophan⁷³; systemic lupus erythematosus from sun, silica, mercury, pesticides, nail polish, paints, dye, canavanine, hydrazine, solvents^{75,76}; lupus, scleroderma, and Paget's disease from pets⁷⁷; granulomatous vasculitis from mercury and lead⁷⁸; primary systemic vasculitis from farming, silica, solvents, and allergy^{70,79}; gout (saturnine) and hyperuricemia with lead intoxication⁸⁰; and rheumatoid arthritis (Caplan's syndrome) with silica, farming, mining, quarrying, electrical work, construction and engine operation, nursing, religious, juridical, and other social science-related work^{81,82} (Table 35-4).

RECREATION- AND SPORTS-RELATED MUSCULOSKELETAL DISORDERS

Do recreational or sports-related activities lead to musculoskeletal disorders? It has been suggested that the risk of joint degeneration is increased by participation in sports that

have high impact levels with torsional loading.⁸³ The presence of prior joint injury, surgery, arthritis, joint instability and/or malalignment, neuromuscular disturbances, and muscle weakness also predisposed to higher risks of joint damage during sports participation.⁸³ Patients with sports injuries (such as from downhill skiing and football) to the anterior cruciate and medial collateral ligaments frequently developed the chondromalacia patellae and radiographic abnormalities of OA (20% to 52%).³³⁻³⁵ Retrospective studies suggest that the development of OA may be associated with varus deformity, previous meniscectomy, and relative body weight.^{84,85} Both partial and total meniscectomies have been associated with degenerative changes. Early joint stabilization and direct meniscus repair surgery may decrease the incidence of premature OA. These observations supported the concept that abnormal biomechanical forces, either congenital or secondary to joint injury, are important factors in the development of exercise-related OA.³³⁻³⁵ Other factors considered important in the development of sports-related OA included certain physical characteristics of the participant, biomechanical and biochemical factors, age, gender, hormonal influences, nutrition, characteristics of the playing surface, unique features of particular sports, and duration and intensity of exercise participation, as has been reviewed extensively elsewhere.³³⁻³⁵ It is increasingly recognized that biomechanical factors have an important role in the pathogenesis of OA.

Is regular participation in physical activity associated with degenerative arthritis? Several animal studies (of tentative scientific relevance, but interesting) have suggested a possible relationship between exercise and OA. For example, it has been stated that the husky breed of dog has increased hip and shoulder arthritis associated with pulling sleds, that tigers and lions develop foreleg OA related to sprinting and running, and that racehorses and workhorses develop OA in the forelegs and hind legs, respectively,⁸⁶ consistent with their physical stress patterns.^{33,35} Rabbits with experimentally induced arthritis in one hind limb did not develop progressive OA when exercised on treadmills,⁸⁷⁻⁹² but sheep in normal health walking on concrete did develop OA.⁹³ Other studies found that beagle dogs running 4 to 20 km a day did not develop OA.⁹⁴ Although

Table 35-4 Other Occupation-Related Rheumatic Diseases

Disease or Syndrome	Occupation or Risk Factor
Reflex sympathetic dystrophy Raynaud's phenomenon	Trauma Vibration Chemicals (polyvinyl chloride)
Autoimmune disease Scleroderma	Teaching school Chlorinated hydrocarbons Organic solvents Silica
Scleroderma-like syndromes	Rapeseed oil L-Tryptophan
Systemic lupus erythematosus	Canavanine, hydrazine, mercury, pesticides, solvents
Lupus, scleroderma, and Paget's disease	Pet ownership
Rheumatoid arthritis (Caplan's syndrome)	Silica
Gout (saturnine)	Lead

these observations were not entirely consistent, they suggested that physical activities in some circumstances might predispose to degenerative joint disease.

There have been some pertinent observations in human studies³³⁻³⁵ (Table 35-5). Wrestlers were reported to have an increased incidence of OA of the lumbar spine, cervical spine, and knees; boxers, of the carpometacarpal joints; parachutists, of the knees, ankles, and spine, which was not confirmed³⁶; cyclists, of the patella; cricketers, of the fingers; basketball and volleyball, of the knees⁵⁵; athletes involved in sports requiring repetitive overhead throwing such as baseball, tennis, volleyball players, and swimmers, of early glenohumeral arthritis⁹⁵; meniscal and anterior cruciate ligament injuries incurred in youth-related sports, of knee

osteoarthritis⁹⁶; soccer players of talar joint, ankle, cervical spine, knee, and hip OA.^{33-35,97-99} Studies of American football players have suggested that they are susceptible to OA of the knees, particularly those who sustained knee injuries while playing football.³⁷ Among football players (average age, 23 years) competing for a place on a professional team, 90% had radiographic abnormalities of the foot or ankle, compared with 4% of an age-matched control population; linemen had more changes than did ball carriers or linebackers, who in turn had more changes than did flankers or defensive backs. All those who had played football for 9 years or longer had abnormal findings on radiography.³³⁻³⁷ Most of these studies suffered in several respects: criteria for OA (or “osteoarthrosis,” “degenerative joint disease,” or

In Bouchard C, Shephard RJ, Stephens T, editors: *Physical activity, fitness, and health. International Proceedings and Consensus Statement*, Champaign, Ill, 1994, Human Kinetics Publishers, pp 712–723; and Panush RS: Does exercise cause arthritis? Long-term consequences of exercise on the musculoskeletal system, *Rheum Dis Clin North Am* 16:827, 1990.

“abnormality”) were not always clear, specified, or consistent; duration of follow-up was often not indicated or was inadequate to determine the risk of musculoskeletal problems at a later age; intensity and duration of physical activity were variable and difficult to quantify; selection bias toward individuals exercising or participating versus those not exercising or participating was not weighted; other possible risk factors and predispositions to musculoskeletal disorders were rarely considered; studies were not always properly controlled, and examinations were not always “blind”; little information regarding nonprofessional, recreational athletes was available; and little clinical information about functional status was provided.

Several studies have examined a possible relationship between running and OA. Uncontrolled observations generally suggested that runners without underlying

biomechanical problems of the lower extremity joints did not develop arthritis at a different rate from a normal population of nonrunners. However, those individuals who had underlying articular biomechanical abnormalities from a previously injured joint (and perhaps elite athletes, particularly women) did appear to be at greater risk for the subsequent development of OA. Early studies showed that groups of long-duration, high-mileage runners and nonrunning control subjects had a comparable (and low) prevalence of OA and suggested that recreational running need not lead inevitably to OA.^{87,100} These observations have generally now been confirmed by others⁸⁸⁻¹⁰² (Table 35-6). Eight- and 9-year follow-up observations were supportive; most of the original runners were still running, with a prevalence of OA that was comparable with that of the control subjects.^{87,89} Perhaps even more significant was the growing evidence

Table 35-6 Studies of Running and Risk of Developing Osteoarthritis

References	No. of Runners	Mean Age (yr)	Mean No. of Years Running	Miles/Wk	Comments
Minor et al (1989) (cited in refs 33-35)	319	NA	NA	NA	OA noted more frequently in former runners (with underlying anatomic “tilt” abnormality—epiphysiolysis) than in nonathletes

Konradsen et al ¹⁰⁴ (1990)	30	58	40	12-24	No clinical or radiographic differences in hips, knees, and ankles between runners and nonrunners
Vingard et al ¹⁰⁹ (1995)	114	50-80	NA	NA	Unvalidated questionnaire reported threefold increase of hip arthrosis in former athletes
Kujala et al ¹⁰⁶ (1994)	342	NA	NA	NA	More former athletes hospitalized with hip OA than expected
Kujala et al ⁹⁷ (1995)	28	60	32	NA	Women soccer players and weightlifters, nonrunners were at risk of premature OA
Panush et al ⁸⁷ (1995)	16	63	22	22	8-yr follow-up of original observations made in 1986 still found no differences between runners and nonrunners
Lane et al ⁸⁹ (1998)	35	60	10-13	23-28	Running did not appear to influence the development of radiographic OA (with possible exception of spur formation in women)

NA, not available; OA, osteoarthritis.

that running and other aerobic exercise protected against the development of disability and early mortality.¹⁰² Former college varsity long-distance runners were compared with former college swimmers in another study¹⁰³; there was no association between moderate levels of running or number of years running and the development of symptomatic OA. Other authors have concluded that running alone does not cause OA; rather, prior injuries and anatomic variances were directly responsible for some of the changes.¹⁰⁰ Prospective studies have found that runners were not at risk for the development of premature OA of the knees.^{92,103-106}

Studies examining hip OA in former athletes^{91,107-110} noted that former champion distance runners had no more clinical or radiographic evidence of OA than did nonrunners.¹⁰⁴ However, another study found more radiographic changes due to degenerative hip disease in former national team long-distance runners than in bobsled competitors and control subjects.¹⁰⁷ In all the subjects studied, age and mileage run in 1973 were strong predictors of radiographic hip OA; for runners, running pace in 1973 was the strongest predictor of subsequent radiographic hip OA in 1988. These authors concluded that high-intensity, high-mileage running should not be dismissed as a risk factor for premature OA of the hip. Other reports found that former top-level soccer players and weightlifters, but not runners, were at risk for the development of knee OA,^{97,110} but it was suggested elsewhere that former athletes seemed to be disproportionately represented in hospital admissions for OA of hip, knee, or ankle.¹¹⁰ A questionnaire of former elite and track-and-field athletes noted they had increased hip OA.¹⁰⁹ Similarly, radiographic OA of the hip and knee was reported in women who were formerly runners and tennis players.¹¹⁰

Cross-sectional studies on the effect of weight-bearing exercise on the development of OA of the hip, knee, or ankle and foot must be interpreted with caution, however. The radiographic scoring methods used by each group of investigators differ, and their reliability has not been adequately tested. This information is important when the major end points in the studies are radiographic features of OA.

PERFORMING ARTS-RELATED MUSCULOSKELETAL DISORDERS

Musculoskeletal problems are common among performing artists. Performing artists—particularly musicians and dancers—have unique medical and musculoskeletal problems that deserve special consideration. Injuries that might be trivial to others may be catastrophic to such artists. These injuries are usually associated with overuse—the consequences of tissues stressed beyond anatomic or normal physical limits. Understanding the technical requirements and biomechanics required in the performance of a craft, as well as the lifestyle required to pursue a successful career in these fields should help physicians appreciate the causative factors that lead to these injuries.

Important principles in approaching such patients follow: (1) Musculoskeletal problems comprise the bulk of health issues for these individuals. (2) Performing artists are usually wary of consulting with physicians (skeptical of their expertise). (3) An appropriate evaluation should be carried out by someone knowledgeable about the technical and

biomechanical requirements of the patient's craft(s). It should consider instrument(s), instrument usage, travel with instruments, shoes, performance surface and setting, practice and performance routines, repertoire, coaches and training/trainers, and lifestyle and psychological factors, as appropriate. (4) Evaluation should include attention to joint laxity and other physical features of the artist, as well as to their relationship to performance, considering those entities encountered as listed in [Table 35-7](#).¹¹¹⁻¹¹⁴ It should assess muscle tension and fatigue. Patients should demonstrate how they use an instrument while both the actively moving body parts and the relatively immobilized parts are examined.^{111,115,116} (5) There should be inquiry about all prescription and nonprescription therapies, nutritional and exercise practices, and nonmainstream treatments. (6) There must be understanding and sympathy for the unique expectations of these performers and expertise in assessing their medical problems and developing treatment plans. (7) Prevention should be emphasized—assuring performance ability, promoting endurance and conditioning, facilitating good posture, protecting joints, maintaining proper ergonomics, and establishing appropriate exercise regimens.^{115,116} (8) Therapeutic interventions will usually be conservative.

Instrumentalists

The frequency of musculoskeletal problems in musicians rivals the frequency of disability in athletes. Up to 82% of orchestral musicians have experienced medical problems related to their occupation, mainly musculoskeletal. Up to 76% of musicians have reported a musculoskeletal issue that is grave enough to influence their ability to perform.^{111,117} Woodwind players and female instrumentalists seemed to be affected more compared with other types of other instrumentalists and male artists, respectively. Muscle-tendon overuse or repetitive stress injuries, nerve entrapment problems, and focal dystonias were most common (see [Table 35-7](#)).^{111,112}

The causes of, mechanisms of, and therapies for these musculoskeletal problems are unclear. Overuse, tendinitis, cumulative trauma disorder, repetitive motion disorder, occupational cervicobrachial disorder, and regional pain syndrome may be critical risk factors in the development of joint laxity in musicians.¹¹⁷ Joint laxity declined with age and was associated with gender, starting earlier in men but persisting in women through their mid-40s. The presence or absence of hypermobility at certain sites was associated with musicians' complaints of associated symptoms. Hypermobility in musicians might produce advantages or disadvantages, depending on the site of the laxity and the instrument played.¹¹⁸ Paganini, with his long fingers and reported hyperextensibility, had a wider finger reach on the violin than his contemporaries, but he may have had a predisposition to OA because of this. Of interest and seemingly unexplained was the high frequency of symptoms among women (68% to 84%); perhaps this is related to their higher incidence of hypermobility.¹¹⁷

Stress is a factor in all performance fields and contributes to motor function problems such as occupational cramps; dealing with this problem often requires the best efforts of a team of physicians and therapists.¹¹⁷⁻¹²⁰

Vocal Artists

Musculoskeletal problems among singers have not been addressed extensively. In a report from the Royal Theater in Copenhagen, the frequency of musculoskeletal problems was the same in both instrumentalists and opera singers. However, singers had more hip, knee, and foot joint complaints, perhaps reflecting the effects of prolonged standing.¹¹⁹

Dancers

Dance has always been viewed as a demanding art form, but only recently have the athletic rigors of this discipline become widely appreciated. Classic ballet ranked first in activities generating physical and mental stress, followed by professional football and professional hockey. The dancer and athlete have much in common, but there are important differences in training and performance technique that influence the nature of their injuries. Other important sociocultural differences affect their care. Professional dancers (as well as musicians and vocalists) have traditionally been unconvinced that most physicians know how to effectively approach the unique issues of dance (and music). Injured dancers seeking care have often been told that the treatment is to stop dancing. Others, seeking assistance with weight control, have been told to gain weight. Dancers frequently underreport their injuries and seek care from nonmedical therapists.

The incidence of dance-related injuries ranges from 17% to 95%.¹²¹ The majority of injuries involved the foot, ankle, and knee. It is difficult to generalize about dance injuries because dance is not a monolithic effort. It is a broad-based hierarchic endeavor in which thousands of local school-based and private amateur dance classes supply a much smaller number of university-based dance programs, which lead finally to relatively few professional dance companies. This system of training encompasses many forms of dance that are highly divergent, ranging from classic ballet to break dancing. Fortunately, most injuries are from overuse and are rarely catastrophic, regardless of the dance style or setting. As with other overuse injuries in sports, they are influenced by a variety of factors that may be classified as intrinsic such as biomechanical and anatomic variations or extrinsic such as those related to occupation or equipment.¹¹⁷

The distribution of injuries is strongly influenced by the type and style of dance and the age and sex of the population.^{118,122} A better understanding of the technical and aesthetic requirements of a dance, as well as the biomechanics involved to perform these requirements, are necessary in

order to appreciate the kind of injuries that can be sustained by dancers. For example, ballet dancers in companies whose choreography emphasizes bravura technique with big jumps and balances are more likely to develop Achilles tendinitis than are those in companies that do not. Men are more likely to have back injuries because of the requisite jumping and lifting, whereas women who dance on pointe are more prone to toe, foot, and ankle problems. Also in ballet, the most important physical feature is proper turnout of the hip, which requires maximal external rotation of the lower extremity that can result in hyperlordosis of the lumbar spine, valgus heel with forefoot pronation, and external rotation of the knee.^{121,123}

Tendinitis of the flexor hallucis longus tendon, commonly known as dancer's tendinitis, may be confused with posterior tibial tendinitis due to the location of pain at the posteromedial ankle.¹²⁴ Other dancer- and environment-related factors that increase the risk of dance-related injuries include nutritional status, improper support from foot-wear and floors, and their rehearsal and performance schedules.^{121,123} Most dance shoes rarely have a shock-absorbing sole, and some dances may be done barefoot.¹²³ Traditionally constructed with paper, glue, and satin or canvas or leather, ballet pointe shoes tend to soften once broken in, thus contributing to ankle injury. Intensive rehearsals before and during the opening months of a performance season, pressures to return to work quickly after an injury, and the "show must go on" mentality must also be considered in the care of dancers.^{117,123} Touring companies may encounter nonflexible surfaces including concrete, predisposing to shin splints and stress fractures. Stress fractures may be associated with the pressure to maintain a certain weight, which may result in amenorrhea, disordered eating, and low bone density. Physicians caring for dancers, particularly ballet dancers at any level, must be aware of the aesthetic pressures for extreme leanness and the potential consequences. Unfortunately, the dance world is not lacking in other serious medical problems including mental illness, drug abuse, and human immunodeficiency virus (HIV) infection.¹¹⁷

KEY POINTS

For nearly half a century, excess rates of cardiovascular disease (CVD) have been reported among patients with inflammatory rheumatic diseases.

Cardiovascular (CV) mortality and morbidity, in particular, ischemic heart disease and heart failure, are significantly higher among persons with rheumatoid arthritis (RA) and/or systemic lupus erythematosus (SLE) and likely other autoimmune disorders compared with persons in the general population of the same age.

With the exception of smoking, the prevalence of traditional CV risk factors is not significantly elevated in persons with RA.

Although the prevalence of some traditional CV risk factors is elevated in SLE patients, these elevations alone are inadequate to explain the excess CV risk in SLE.

Some traditional risk factors (e.g., dyslipidemia) behave in a paradoxical manner in RA and SLE.

The systemic inflammation and immune dysfunction that characterize rheumatic diseases appear to be a driver of CV risk in these patients.

The relationship between antirheumatic drugs and CV risk is difficult to disentangle due to confounding by indication/contraindication.

For nearly half a century, excess rates of cardiovascular disease (CVD) have been reported among patients with inflammatory rheumatic diseases.¹⁻⁵ More recently, the discovery of the inflammatory and immune mechanisms underlying atherosclerosis has spurred renewed interest in the association between CV risk and the rheumatic diseases. In this chapter we review the risks of cardiovascular comorbidity in the rheumatic diseases, focusing on rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). We also discuss the contribution of traditional and nontraditional cardiovascular risk factors to the observed excess CVD risk.

CARDIOVASCULAR MORTALITY

Rheumatoid Arthritis

The mortality of patients with established RA is known to be higher than that of the general population.⁶⁻¹⁰ Approximately 50% of all deaths in RA subjects are attributable to cardiovascular causes including ischemic heart disease (IHD) and stroke,¹¹ and CVD appears to occur earlier in individuals with RA. The latter observation is consistent

Cardiovascular Risk in Rheumatic Disease

SHERINE E. GABRIEL • DEBORAH SYMMONS

with the recent hypothesis of accelerated aging in RA in general.¹² More than 50% of premature deaths in RA are due to CVD. A meta-analysis of 24 mortality studies in RA, published between 1970 and 2005, reported a weighted combined all-cause standardized mortality ratio (met-SMR) of 1.50 (95% confidence interval [CI],) with similar increases for IHD (met-SMR, 1.59; 95% CI, 1.46 to 1.73) and stroke (met-SMR, 1.52; 95% CI, 1.40 to 1.67); and for men (met-SMR, 1.45) and women (met-SMR, 1.58).¹³ Moreover, patients with RA frequently experience “silent” IHD and/or silent myocardial infarction (MI), showing no symptoms at all before a sudden cardiac death. Sudden cardiac deaths are almost twice as common in RA patients as in the general population (hazard ratio [HR], 1.99; 95% CI, 1.06 to 3.55).¹⁴

The excess CV mortality in RA may be confined to, or at least substantially higher in, subjects who are rheumatoid factor (RF) positive.^{3,15-18} The link may be even stronger with anticitrullinated protein antibody (ACPA) positivity.¹⁹ As might be expected, the relative risk of CV mortality is highest in younger age groups (those younger than 55 in whom controls have lower absolute risk and therefore in whom the distinction from those with RA is likely to be exacerbated) and in women, while the attributable risk is highest in the oldest age groups and in men.^{17,20,21}

Controversy persists regarding how soon after symptom onset the excess CV mortality risk becomes apparent and/or whether there is a secular trend toward improving CV mortality in RA (as is seen in the general population). This may be partially explained by differences in the period of follow-up (i.e., follow-up starting from the time of symptom onset, from a physician’s diagnosis of RA, from the date of fulfillment of American College of Rheumatology (ACR) criteria, or other diagnostic criteria). The latter may not occur until some years after the first symptoms. In the Norfolk Arthritis Register (NOAR) the excess CV mortality is detectable beginning around 7 years after symptom onset.¹⁵ In a Dutch inception cohort of 1049 RA patients recruited between 1985 and 2007, excess mortality became apparent around 10 years after diagnosis (with all subjects having <1-year symptom duration).²² Unfortunately, there appears to be little evidence that CV mortality has improved significantly. A meta-analysis that included 17 studies (91,916 patients) reported CV mortality risk between 1976 and 2007, showing no trend toward improving CV SMR with time.^{23,24}

Systemic Lupus Erythematosus

As first described by Urowitz and colleagues² in 1976, mortality in SLE appears to follow a bimodal pattern, with an early peak in mortality (within 1 year of diagnosis) and a

later peak occurring >5 years after diagnosis). Reported survival in the first 5 years of SLE has improved considerably from about 50% in the 1950s to more than 90% in the 1990s.²⁵ However, there is some question as to whether this may be due, at least in part, to earlier diagnosis and improved ascertainment of mild cases. In the Toronto lupus cohort of 1241 patients recruited between 1970 and 2005, the SMR improved from 13.84 (range, 9.78 to 19.76) during 1970 to 1978 for those who entered the cohort in that decade to 3.81 (range, 1.98 to 7.32) during 1997 to 2005 in those who entered the cohort in that time period.²⁶ The SMR during 1997 to 2005 was similar for patients regardless of their disease duration, ranging from 3.23 for those who had entered the cohort in 1970 to 1978 to 3.93 for those who had entered the cohort in 1988 to 1996. Similarly, evidence from Olmsted County, Minnesota showed an SMR of 2.70 with significant improvement in survival in recent decades.²⁷ In a study of 434 female lupus patients from Seoul, Korea followed from 1992 to 2002, the SMR was 3.02 (95% CI, 1.45 to 5.55).²⁸ No study has been large enough to permit study of cause-specific SMR.

CARDIOVASCULAR COMORBIDITY

Rheumatoid Arthritis

Ischemic Heart Disease

Patients with RA are at increased risk of IHD.^{5,14,20,24,29-32} Data from the Rochester Epidemiology Project have shown that, in the 2-year period immediately preceding the fulfillment of the ACR 1987 criteria, RA patients were more likely to experience hospitalization for MI (odds ratio [OR], 3.17; 95% CI, 1.16 to 8.68) and unrecognized ("silent") MI (OR, 5.86; 95% CI, 1.29 to 26.64) than age- and sex-matched controls. The increased risk of unrecognized MI persisted after the diagnosis of RA (HR, 2.13; 95% CI, 1.13 to 4.03). Holmqvist and colleagues failed to demonstrate a statistically significant elevated increase in MI, angina, or heart failure before the onset of symptoms in two large Swedish cohorts,³³ although trends toward such elevation were reported. As in studies of mortality, these results suggest that accelerated atherosclerosis begins at the onset of RA symptoms, or even earlier, and not at the time of diagnosis or later in the disease course.

Patterns of clinical care and outcome after MI may vary in persons with RA when compared with the general population. Some evidence suggests that although RA patients receive similar MI care to non-RA patients, they experience higher rates of heart failure and death after MI.^{32,34,35} However, others have recently reported that RA patients who experience acute MI receive acute reperfusion and secondary prevention medications (including β -blockers and lipid-lowering agents) less frequently than controls.³⁶ Moreover, another group recently reported that among patients with MI, those with RA were more likely to undergo thrombolysis and percutaneous coronary intervention (PCI) but less likely to receive medical therapy or coronary artery bypass grafting, or both.³⁷ That study also suggested that patients with RA may have an in-hospital survival advantage, particularly those undergoing medical therapy and PCI, though potential confounding could not be ruled out.

Figure 36-1 Comparison of the cumulative incidence of congestive heart failure in the rheumatoid arthritis (RA) cohort and the non-RA cohort, according to the number of years since the index date (incidence date for the RA patients), adjusting for the competing risk of death. (From Nicola PJ, Maradit-Kremers H, Roger VL, et al: *The risk of congestive heart failure in rheumatoid arthritis: a population-based study over 46 years*, *Arthritis Rheum* 52(2):412-420, 2005. Permission to reprint from John Wiley & Sons.)

Heart Failure

Patients with RA are also at increased risk of developing heart failure compared with the general population.^{38,39} In the Rochester RA cohort, the cumulative incidence of congestive heart failure (CHF; defined according to the Framingham criteria) at 30-year follow-up was 34% compared with 25% in the non-RA cohort (Figure 36-1; $P < 0.001$). Even after adjustment for demographics, CV risk factors, and IHD, patients with RA had almost twice the risk of developing CHF as non-RA subjects (HR, 1.87; 95% CI, 1.47 to 2.39). This increased risk of CHF appeared to be predominantly in the subgroup of RA patients who were RF positive (HR in RF-positive patients, 2.59; 95% CI, 1.95 to 3.43 vs. 1.28 in RF-negative patients; 95% CI, 0.93 to 1.78).

The clinical presentation of CHF in patients with RA differs from CHF in non-RA patients.⁴⁰ RA patients with CHF are less likely to be obese, be hypertensive, or have clinical IHD. Moreover, RA patients with CHF are less likely to have typical signs and symptoms. Importantly, the proportion of CHF patients with preserved ejection fraction (>50%) is significantly higher among RA compared with non-RA patients.⁴⁰ It has also been shown that RA patients with CHF tend to be investigated and managed less aggressively.⁴⁰ Finally, RA patients with CHF also appeared to have poorer outcomes, experiencing approximately twice the risk for death in the period immediately after detection of heart failure compared with non-RA patients.⁴¹

Systemic Lupus Erythematosus

Ischemic Heart Disease

Accelerated atherosclerosis is an established complication of SLE.^{30,42-49} The prevalence of atherosclerotic vascular events varies from 1.8% in early disease to more than 27%

later in the course of SLE.^{47,50-52} The majority of studies reported increased risk of MI ranging from 2- to greater than 10-fold in various SLE patient groups compared with the general population.^{30,45,47,53} This increased relative risk of MI is particularly apparent in younger SLE patients. The most striking example comes from the University of Pittsburgh lupus cohort, where women with SLE aged 35 to 44 were more than 50 times as likely to have an MI compared with women without SLE in the Framingham Offspring study (relative risk [RR], 52.43; 95% CI, 21.6 to 98.5).⁴⁷ Furthermore, the majority (67%) of women with SLE were younger than 55 years of age at the time of their first cardiac event. In addition, a greater than twofold increased risk of hospitalizations for MI has been reported in young women with SLE between 18 and 44 years of age compared with those without SLE (OR, 2.27; 95%CI, 1.08 to 3.46).⁴⁹

A recent study of patients undergoing coronary revascularization procedures found no significant differences in the mean percent of coronary stenosis and total occlusion in SLE versus non-SLE subjects.⁵⁴ Except for the increased likelihood of lesions confined to the left anterior descending artery in SLE versus non-SLE subjects (42.3% vs. 19.3%; $P = 0.003$), the pattern of coronary involvement including artery dominance and prevalence of multivessel disease appeared similar in SLE versus non-SLE subjects. However, the study reported significantly worse cardiovascular outcomes at 1 year following PCI in SLE versus non-SLE subjects including higher risk of MI (15.6% vs. 4.8%; $P = 0.01$), and repeat PCI (31.3% vs. 11.8%; $P = 0.009$) in SLE, even after adjustment for important co-variables.^{54,55} Given increased vulnerability of atherosclerotic plaque in SLE, which is associated with the risk of occlusive events irrespective of size of the plaque, these findings suggest an increased risk of unfavorable cardiovascular events in SLE patients versus non-SLE subjects with a seemingly similar pattern of coronary involvement.⁵⁶

In a large population-based study of patients hospitalized in California with acute MI from 1996 to 2000, in-hospital mortality and length of stay were essentially similar in patients with SLE compared with those who did not have SLE adjusting for age, race, ethnicity, type of medical insurance, and Charlson Index. In contrast, data from the 1993 to 2002 U.S. Nationwide Inpatient Sample showed significantly increased rates of in-hospital mortality (RR, 1.46; 95% CI, 1.31 to 1.61) and prolonged hospitalization (RR, 1.68; 95% CI, 1.43 to 2.04) for acute MI in SLE compared with controls, adjusting for age, sex, race/ethnicity, income, and CHF.⁵⁵ Some differences in methodology (i.e., smaller sample size and older age of SLE patients and control subjects in the earlier study and shorter observation period in the later study) may at least in part explain these contrasting results. Considering the presence of myocardial involvement, chronic systemic inflammation, vasculitis, and hyperviscosity syndrome in SLE, worse outcomes following acute coronary events and associated interventions can reasonably be expected.⁵⁷ However, this requires further study.

Heart Failure

The risk of CHF and related hospitalization in SLE appears to be substantially increased.^{49,55,58} In particular, young

women with SLE between 18 and 44 years of age have a greater than 2.5-fold increased risk of hospitalization for CHF versus those who did not have SLE, even after adjustment for age, race, insurance status, hospital characteristics, and the presence of hypertension, diabetes mellitus, and chronic renal failure.⁴⁹ Consequently, CHF accounted for a substantially higher percent of hospitalizations in women with SLE versus those without SLE within this age group (1.32% vs. 0.35%, respectively; $P < 0.0001$). The nature of CHF in SLE is likely multifactorial, only partly attributable to atherosclerosis.^{52,59,60} The presentation of CHF in SLE may vary from severe overt CHF to insidious myocardial involvement.⁵⁹⁻⁶³ Finally, mortality in SLE patients with CHF is significantly higher than in those without CHF (17.9% vs. 5.8%; $P < 0.001$) and approximates 3.5-fold as compared with the general population.^{55,59}

TRADITIONAL RISK FACTORS FOR CARDIOVASCULAR DISEASE

The role of traditional risk factors in the development of CVD in persons with RA and SLE is an area of active research. One possible explanation for the increase in CVD seen in RA and SLE could be that the traditional CVD risk factors are more common in these diseases or that they are as common but are more deleterious. Alternatively, the excess CVD risk may be explained by the adverse impact of the inflammation and immune changes of RA and SLE on the vessel wall. In fact, the polarization of these possible explanations is oversimplistic because traditional risk factors and inflammation are intimately interconnected and may act synergistically.

Population studies have elucidated the role of a number of “traditional” risk factors including increasing age, male gender, smoking, hypertension, hypercholesterolemia, and diabetes in the development of CVD in persons with RA and SLE. These factors have been combined into a number of scores for estimating the risk of future CVD events in the general population. The most well-known of these is the Framingham risk score, which provides an estimate of the 10-year risk of a future CVD event for an individual subject. More recently, body composition (in particular, visceral adiposity) and physical inactivity have also been identified as traditional risk factors for CVD for use in the general population.

Traditional Cardiovascular Risk Factors

Smoking in Rheumatoid Arthritis

Smoking is a known risk factor for the development of RA, in particular RF and ACPA-positive RA. Thus as expected, there is a higher prevalence of current smokers and ex-smokers among subjects with RA than among the general population. In a meta-analysis of four case-control studies (1415 RA patients) of traditional CVD risk factors in RA, the prevalence of smoking was found to be significantly higher than in controls (OR, 1.56; 95% CI, 1.35 to 1.80).⁶⁴ Smokers with RA also appear to have a worse prognosis in terms of RF titers, disability, radiographic damage, and treatment response.⁶⁵ There is a known interaction among

smoking, human leukocyte antigen (HLA) DR1 shared epitope (SE) alleles, and the production of ACPA⁶⁶ and among smoking, ACPA, and the SE in premature CVD mortality in RA.¹⁹

Smoking in Systemic Lupus Erythematosus

In a case-control study involving 250 women with SLE, smoking was no more common than in the general population (RR, 0.86; 95% CI, 0.59 to 1.24).⁶⁷ Nevertheless, smoking was a risk factor for vascular events in the cohort overall and in the inception subcohort.⁵¹

Hypertension in Rheumatoid Arthritis

Hypertension is common in patients with RA, but it remains unclear whether it is more common than in the general population. A recent meta-analysis of seven case-control studies (1053 RA patients) found the prevalence of hypertension to be the same in RA patients as in controls (OR, 1.09; 95% CI, 0.91 to 1.31).⁶⁴ There is, however, some evidence for underdiagnosis and undertreatment of hypertension in RA patients.⁶⁸ Multiple other factors may influence blood pressure control in persons with RA including physical inactivity, obesity, specific genetic polymorphisms, and several antirheumatic medications including nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, leflunomide, and cyclosporine.

Hypertension in Systemic Lupus Erythematosus

Hypertension is substantially more common in women with lupus than in the general population. A case-cohort control study found the relative risk of hypertension in women to be 2.59 (95% CI, 1.79 to 3.75).⁶⁷ Hypertension has been noted to be a predictor of mortality and vascular events in lupus in a number of studies.^{50,69} Hypertension was found to be a predictor of vascular events in the total Toronto cohort of 1067 patients but not in the 561 patients in the inception cohort.⁵¹

Dyslipidemia in Rheumatoid Arthritis

Although findings have been somewhat inconsistent, hyperlipidemia appears to have a paradoxical relationship with CV risk in persons with RA,⁷⁰⁻⁷⁴ namely decreased lipid levels associated with increased CV risk. Serum levels of total cholesterol and low-density lipoprotein (LDL)

cholesterol decline precipitously during the 3- to 5-year period before RA incidence,⁷⁵ and lower total and LDL cholesterol levels have been shown to be associated with higher CV risk.⁷⁶ Suppression of total and LDL cholesterol levels during acute or chronic high-grade inflammation is well described, as is a proportionately greater suppression of high-density lipoprotein (HDL) cholesterol, resulting in a disadvantageous atherogenic index (total-to-HDL cholesterol ratio).⁷⁷ This may explain the fact that hyperlipidemia (high total or LDL cholesterol) appears to be less common in RA compared with non-RA subjects.^{70,78,79} Dyslipidemia (alterations of individual lipid components and their ratios as defined by specific criteria) may affect up to half of all RA patients in hospital care.⁸⁰ A recent meta-analysis showed that RA is associated with an abnormal lipid pattern, principally low levels of HDL cholesterol.⁸¹ Lipid alterations appear to predate the diagnosis of RA. Serum levels of total cholesterol and LDL cholesterol decline precipitously during the 3- to 5-year period before RA diagnosis.^{75,82} In vitro animal model and human in vivo studies in subjects without RA clearly demonstrate that the interplay between inflammation and lipid components is far more complex than simple alterations of their serum levels⁸³ (Figure 36-2). For example, acute phase proteins such as serum amyloid A and phospholipase A₂ can alter HDL composition and function, whereas inflammation may have profound effects on enzymes fundamental to the metabolism of HDL (e.g., hepatic lipase) or indeed the enzymatic content of HDL itself (e.g., reduced paraoxonase); this may increase susceptibility to oxidation and convert HDL to a more pro-oxidant, pro-atherogenic complex. Such inflammation-induced alterations of structure and function are not confined to HDL but also involve triglycerides and LDL; they require further study, specifically in RA and in the context of disease control through nonbiologic and biologic disease-modifying antirheumatic drugs (DMARDs).⁸⁴ To date, several studies suggest antirheumatic therapy mediates effects on lipid levels including glucocorticoids, hydroxychloroquine, gold, cyclosporine, and the biologics anti-tumor necrosis factor (TNF), rituximab, and tocilizumab: these are generally short-term studies of small numbers of patients addressing predominantly serum levels rather than other modifications or mechanisms.^{83,85} Multiple other factors are involved in lipid regulation and function including physical activity, adiposity, diet, alcohol intake, and smoking. However, their effects have not been assessed in any detail in persons with RA. Similarly, the importance of genetic regulation of lipid metabolism,

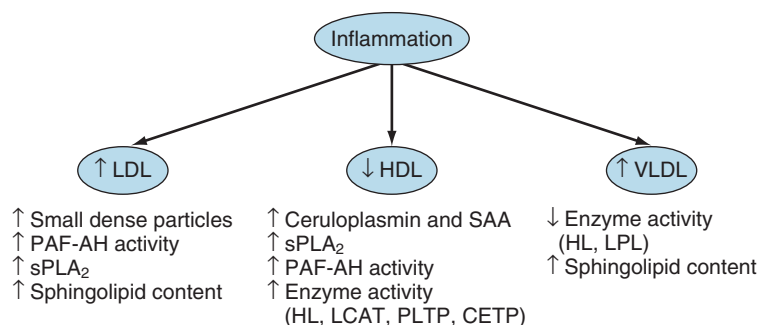

Figure 36-2 The effects of inflammation on lipid structure and function. CETP, cholesterol ester transfer protein; HDL, high-density lipoprotein; HL, hepatic lipase; LCAT, lecithin-cholesterol acyltransferase; LDL, low-density lipoprotein; LPL, lipoprotein lipase; PAF-AH, platelet activating factor acetylhydrolase; PLTP, phospholipid transfer protein; SAA, serum amyloid A; sPLA₂, secretory phospholipase A₂; VLDL, very-low-density lipoprotein. (From Toms TE, Symmons DP, Kitas GD: *Dyslipidaemia in rheumatoid arthritis: the role of inflammation, drugs, lifestyle and genetic factors*, Curr Vasc Pharmacol 8:301-326, 2010. Permission to reprint from Bentham Science Publishers Ltd.)

particularly in the context of gene-environment interactions, has not been addressed in the RA population. This may be particularly important because lipid alterations appear to predate the diagnosis of RA.

It is well known that HDL cholesterol is normally protective against atherosclerosis. However, in some circumstances such as after infection or postoperatively, HDL may become “proinflammatory” by virtue of altered molecular composition. McMahon and colleagues⁸⁶ reported that around 20% of women with RA had proinflammatory HDL (piHDL) compared with only 3.1% in the normal population. Unlike normal HDL, piHDL does not protect LDL from oxidation. Lipoprotein (a) levels are also reported to be increased in RA subjects and associated with increased CVD risk.⁸⁷ In the Apolipoprotein-related MOrtality RiSk (AMORIS) study the risk of MI was 60% higher among the 1779 subjects who had RA compared with the 478,627 subjects without RA.⁷⁰ However, although total cholesterol and triglyceride levels were associated with the development of acute MI in subjects without RA, this was not the case in those with RA.

Dyslipidemia in Systemic Lupus Erythematosus

As in RA, inflammation may have a deleterious effect on the atherogenic index in SLE. However, although hypercholesterolemia is no more common in SLE than in the general population,⁶⁷ when present it is associated with an increased risk of vascular events.^{47,50} Hypercholesterolemia was a risk factor for future cardiovascular events in the total Toronto cohort but not in the inception cohort.⁵² Again, this may be a reflection of aggressive management of hyperlipidemia in the inception cohort. In the United Kingdom General Practice Research Database the combination of SLE and hypercholesterolemia was associated with an 18-fold increased risk of MI compared with the general population.³⁰ As in RA, patients with SLE may have increased levels of proinflammatory HDL.⁸⁶

Diabetes in Rheumatoid Arthritis

A recent meta-analysis of seven case-control studies (1230 RA patients) reported that the prevalence of diabetes was increased in comparison with controls (OR, 1.74; 95% CI, 1.22 to 2.50).⁶⁴ Abdominal obesity, antihypertensive medication, disease activity, and use of corticosteroids all affect glucose metabolism in RA.⁸⁸ On the other hand, use of hydroxychloroquine has been shown to reduce the risk of developing diabetes in RA by 77%.⁸⁹

Diabetes in Systemic Lupus Erythematosus

The incidence of diabetes mellitus is substantially increased in women with SLE (RR, 6.00; 95% CI, 1.36 to 26.53).⁶⁷ However, diabetes was not a predictor of vascular events in either the entire Toronto cohort or the inception subcohort.⁵²

Body Composition

Escalante and colleagues⁹⁰ reported a “paradoxical effect of BMI on survival in persons with RA” demonstrating that,

as BMI declined, so did survival probability among study subjects with RA. Among persons without RA, low BMI is not associated with increased risk of CV death. However, among RA patients, low BMI, which may indicate uncontrolled active systemic inflammation, is associated with a threefold increased risk of CV death⁹¹ even after adjustment for cardiac history, smoking, diabetes mellitus, hypertension, and malignancy.

Obesity is associated with an increased frequency of traditional CV risk factors in patients with RA⁹² as in the general population. In particular, abdominal fat is associated with insulin resistance and inflammatory load in patients with RA⁹³ and there is new evidence that in such patients, abdominal fat is distributed differently between the visceral and subcutaneous compartments, with visceral fat more strongly associated with cardiometabolic risk.⁹⁴ Adipose tissue is metabolically active and, through a network of adipocytokines, regulates not only energy intake and expenditure but also inflammation. Interventions to reverse rheumatoid cachexia, control obesity, and regulate insulin resistance including comprehensive physical exercise programs in RA have been little studied. A sedentary lifestyle is common in patients with SLE.^{50,67}

Impact of Traditional Cardiovascular Risk Factors in Rheumatoid Arthritis

The absolute CV risk in RA subjects has been estimated to be similar to that in non-RA subjects who were approximately 10 years older.⁹⁵ Further studies suggest that CV disease and CV death in RA are of similar magnitude to that seen in patients with type II diabetes mellitus⁹⁶ (Figure 36-3). This information, together with the findings that traditional CV risk factors behave differently in RA subjects, suggest that risk scores based on traditional CV risk factors alone are likely to inaccurately estimate CV risk in RA. Indeed, recent studies have reported that such risk scores (e.g., Framingham) can underestimate CV risk fivefold in some RA patients.⁹⁷ All this clearly highlights the need for RA-specific risk prediction tools. To this end, the European League against Rheumatism (EULAR) has recently proposed the application of a $\times 1.5$ multiplier to the risk calculated on the basis of standard algorithms.⁹⁸ This approach, although appealing in its pragmatism, requires validation.

Impact of Traditional Cardiovascular Risk Factors in Systemic Lupus Erythematosus

On average, persons with SLE and CVD have one less classic risk factor than persons in the general population with CVD.^{51,99} Esdaile and colleagues calculated the baseline 10-year CHD and stroke risk using the Framingham score for all lupus patients attending a lupus clinic in Montreal. Even after adjusting for the Framingham score, patients still had a 7.5- to 17-fold increased risk of cardiovascular events.⁴⁵ Although lupus patients with vascular events were found to have a higher number of traditional risk factors than those without events, they did not have a higher Framingham risk score. This suggests that the relative importance of the individual risk factor differs between lupus patients and the general population.

Figure 36-3 Cardiovascular event-free probability to 3 years among nondiabetic controls (red line), patients with type 2 diabetes mellitus (DM) (blue line), and nondiabetic patients with rheumatoid arthritis (RA) (green line). The hazard ratios for the nondiabetic controls and patients with RA as compared with nondiabetic controls were as follows: for patients with type 2 DM, 2.0 (95% confidence interval [95% CI], 1.1 to 3.7); for nondiabetic patients with RA, 2.2 (95% CI, 1.3 to 3.6). Differences were estimated from age- and sex-adjusted Cox proportional hazards models. (From Peters MJ, van Helm VP, Voskuyl AE, et al: *Does rheumatoid arthritis equal diabetes mellitus as an independent risk factor for cardiovascular disease? A prospective study*, *Arthritis Rheum* 61(11):1571–1579, 2009. Permission to reprint from John Wiley & Sons.)

Impact of Rheumatoid Arthritis Disease Activity and Severity on Cardiovascular Comorbidity

A number of studies have linked the risk of CV comorbidity with markers of RA disease activity such as baseline C-reactive protein,¹⁶ last recorded erythrocyte sedimentation rate (ESR),¹⁰⁰ and an ESR greater than or equal to 60 mm/hr on three or more occasions.¹⁴ In a study of 231 male veterans with RA, a baseline disease activity score (DAS28) of 5.1 or greater predicted CV events (HR, 1.3; 95% CI, 1.1 to 1.6).¹⁰¹ Markers of disease severity such as RF, ACPA, physical disability, destructive changes on joint radiographs, rheumatoid nodules, vasculitis, rheumatoid lung disease, and corticosteroid use are statistically significantly associated with increased risk of CV events and/or death even after adjustment for traditional CV risk factors.^{19,95,102–108} Analyses of ESR levels in 172 RA cases with heart failure demonstrated that the proportion with significantly elevated ESR (≥ 40 mm/hr) was highest during the 6-month period before CHF diagnosis as compared with any other time over the entire follow-up period.¹⁰² RF^{103,105} and anti-nuclear antibody^{103,109} are risk factors for MI, CHF, and/or vascular disease even in subjects without RA, suggesting that immune dysregulation may promote CV risk not only in persons with rheumatic disease but also in the general population.¹⁰³

Impact of Systemic Lupus Erythematosus Disease Activity and Severity on Cardiovascular Comorbidity

Various markers of inflammation and organ damage have been found to be associated with CV events in SLE including renal, neuropsychiatric, and vasculitic disease.⁵¹ In addition, SLE may be associated with thrombotic tendency and this, too, may contribute to the burden of CV disease.

Medications as Cardiovascular Risk Factors

Medications used for the treatment of rheumatic diseases may also affect CV risk. Because of the common use of NSAIDs and concerns surrounding CV risk with their use, this has been extensively studied. Although some evidence indicates that NSAID use¹¹⁰ is not associated with increased CV risk in RA, a recent network meta-analysis of 31 trials in 116,429 patients concluded that there is little evidence to suggest that any of the investigated drugs (i.e., naproxen, ibuprofen, diclofenac, celecoxib, etoricoxib, rofecoxib, or lumiracoxib) are safe.¹¹¹ It is important to note, however, that the study populations in these trials consisted largely of patients with osteoarthritis and other musculoskeletal conditions rather than RA. In contrast, use of DMARDs (methotrexate in particular) and/or biologic agents has been suggested to decrease CV risk^{112–116} in patients with RA. This is believed to be due to effective long-term control of systemic inflammation. Although these findings are intriguing, they cannot be considered definitive evidence that these agents reduce CV risk due to confounding by indication and/or contraindication.

Statins have established effectiveness in the primary prevention of CV events in the general population and at-risk subpopulations (e.g., patients with diabetes mellitus). These agents have both lipid-modifying and anti-inflammatory effects. However, their role in RA is only more recently being explored¹¹⁷; thus utilization of statins is low in patients with RA, even in those at high risk.⁸⁰ A number of studies are ongoing to resolve these questions such as TRACE-RA (Trial of Atorvastatin in the Primary Prevention of Cardiovascular Endpoints in Rheumatoid Arthritis), a multicenter, placebo-controlled study, aiming to enroll more than 3000 patients with RA without overt CV disease.¹¹⁸

Cardiovascular Risk in Other Inflammatory Rheumatic Diseases

Although the evidence for an increased risk of CV events is strongest for RA and SLE, emerging literature suggests that psoriatic arthritis and ankylosing spondylitis may also be associated with excess CV risk. The literature is conflicting regarding whether or not psoriasis is a risk factor for CVD. A large Danish nationwide study demonstrated a small but significant excess CV risk associated with psoriasis,¹¹⁹ whereas a large U.S. cohort study failed to demonstrate such a risk even with severe psoriasis.¹²⁰ Psoriatic arthritis has been shown to be associated with subclinical atherosclerosis after adjusting for traditional CV risk factors.¹²¹ There are also reports suggesting that hyperuricemia, commonly associated with psoriatic arthritis, may be correlated with subclinical atherosclerosis.¹²² These findings are further confounded by the complex risk factor profile among psoriasis patients who are more likely to be smokers and diabetics and have metabolic syndrome and atherogenic dyslipidemia.¹²³ Further research is necessary to disentangle these factors in order to determine the independent impact of psoriasis and psoriatic arthritis on CV risk.

Elevated rates of cardiovascular morbidity and mortality have also been observed in ankylosing spondylitis (AS), although less than that observed with RA.¹²⁴ In addition,

AS appears to have a similar abnormal lipid profile to that seen in RA.¹²⁵ As in RA, there is growing evidence indicating subclinical vascular disease and endothelial dysfunction in AS.¹²⁶ Thus although the body of evidence is far smaller in AS than in RA, there appear to be substantial similarities in the findings of these two conditions.

There is also limited evidence describing excess CV risk with other, rarer rheumatic conditions. Nonetheless, taken together, these findings support the association between chronic inflammatory rheumatic diseases and an excess risk of CV morbidity and mortality. Additional research is necessary to better elucidate the relative contribution of disease factors, treatments, and underlying risk factors on CVD in persons with rheumatic diseases.

Connection to the Clinic

Physicians who care for patients with rheumatic diseases should manage these individuals as a high cardiovascular risk subgroup, regardless of their traditional risk factor parameters.

Future Directions

1. Large multicenter randomized clinical trials are necessary to establish the cardiovascular (CV) risks and/or benefits associated with antirheumatic drugs.
2. Disease-specific risk assessment tools are necessary to accurately determine an individual patient's CV risk in the clinical setting.

KEY POINTS

Risk of malignancy, especially lymphoproliferative malignancy, is increased in autoimmune rheumatic diseases.

The occurrence of cancer in patients with rheumatic diseases adversely affects quality of life and life expectancy compared with the general population.

This risk is related to the pathobiology of the underlying rheumatic disease, including the inflammatory burden, immunologic defects such as overexpression of *Bcl-2* oncogenes, traditional risk factors such as smoking, and, in some cases, associated viral infection.

Several of the immunomodulatory treatments used in the management of autoimmune disease, especially chemotherapeutic agents, are associated with an increased risk of cancer.

The decision to use immunomodulating therapies in patients with rheumatic disease must take into account host and environmental risk factors for cancer. Effective screening and monitoring strategies can markedly reduce the risk of cancer in these patients.

Systemic rheumatic diseases have been associated with an increased risk of development of malignancy. This increased risk is the result of fundamental underlying immunologic effects of autoimmunity on cancer risk and on the risk of cancers associated with drug treatments for rheumatic diseases.

Accelerated growth of cancer cells in immunodeficient mice and increased risk of cancer in heavily immunosuppressed transplant patients have shaped the perception of the immune system as a potent barrier against neoplasms.^{1,2} It might be expected that immunosuppressive treatment would inevitably result in effects favoring malignant cell growth. However, emerging evidence supports the seemingly paradoxical notion perhaps formulated first by Rudolph Virchow in 1863 that inflammation is a critical component of cancer initiation and progression, and that reduction of systemic inflammation may reduce cancer risk in these conditions.³

Assessment of cancer risk in rheumatic diseases must be weighed against the lifetime risk of developing cancer, which is approximately 20% in Western Europe and North America, with 5% of the general population having current cancer or a history of cancer.⁴ Approximately 1 in 10 women will develop breast cancer, and as many as 1 in 8 men will develop prostate cancer, 1 in 25 colorectal cancer, 1 in 40 lung cancer, and approximately 1 in 100 lymphoma or other lymphoproliferative malignancy.⁴

Cancer Risk in Rheumatic Diseases

ERIC L. MATTESON

The combination of increased risk for some and decreased risk for other types of cancers in different rheumatic diseases may result in a neutral effect for malignancies in general, emphasizing why, from a clinical standpoint, it is important to identify risks pertaining to specific cancers, which may be uncommon. The statistical approach for capturing differences in sparse event data, particularly when malignancy is not a prespecified study outcome, and assumptions of proportional hazards models and stable frequencies of events over time for a nonlinear risk such as cancer can lead to major errors in interpretation.⁵

MALIGNANCY IN AUTOIMMUNE RHEUMATIC DISEASES

Several of the rheumatic diseases, particularly lymphoproliferative disorders, appear to be associated with increased risk of malignancy. A list of rheumatic diseases that have been associated with malignancy is provided in [Table 37-1](#). In a global assessment of susceptibility to Hodgkin's lymphoma using population-based linked registry data from Sweden and Denmark, 32 autoimmune and related conditions were identified from hospital diagnoses in 7476 case subjects with Hodgkin's lymphoma, 18,573 matched control subjects, and more than 86,000 first-degree relatives of case and control subjects. Significantly increased risks of Hodgkin's lymphoma were associated with a personal history of autoimmune disorders, including rheumatoid arthritis (odds ratio [OR], 2.7; 95% confidence interval [CI], 1.9 to 4.0), systemic lupus erythematosus (OR, 5.8; 95% CI, 2.2 to 15.1), sarcoidosis (OR, 14.1; 95% CI, 5.4 to 36.8), and immune thrombocytopenic purpura (OR, ∞; *P* = 0.022). A statistically significant increase in the risk of Hodgkin's lymphoma was associated with family histories of sarcoidosis (OR, 1.8; 95% CI, 1.01 to 3.1) and ulcerative colitis (OR, 1.6; 95% CI, 1.02 to 2.6).⁶ Shared susceptibility for autoimmune disease and lymphoma is suggested by the association between personal and family history for some of these disorders, particularly sarcoidosis, and a statistically significantly increased risk of Hodgkin's lymphoma, but was not confirmed in a large registry-based study of patients with early rheumatoid arthritis from Sweden.^{6,7}

The occurrence of cancer has a profound effect on the already compromised quality of life of patients with rheumatic diseases and may affect survivorship. A population-based study of cancer survival in patients with inflammatory arthritis from Great Britain suggests decreased survival compared with the general population.⁸ Survivorship related to the occurrence of cancer in this population was unrelated to disease-modifying antirheumatic drug (DMARD) exposure.⁸

Table 37-1 Rheumatic Diseases Associated with Malignancy

Connective Tissue Disease	Malignancy	Associated Factors	Clinical Alert
Sjögren's syndrome	Lymphoproliferative disorders	Glandular features: lymphadenopathy, parotid or salivary enlargement Extraglandular features: purpura, vasculitis, splenomegaly, lymphopenia, low C4 cryoglobulins	Clues to progression from pseudolymphoma to lymphoma include worsening of clinical features, disappearance of rheumatoid factor, and decline of IgM
Rheumatoid arthritis	Lymphoproliferative disorders	Presence of paraproteinemia, greater disease severity, longer disease duration, immunosuppression, Felty's syndrome	Rapidly progressive; refractory flare in long-standing rheumatoid disease may suggest an underlying malignancy
Systemic lupus erythematosus (SLE)	Lymphoproliferative disorders	—	Non-Hodgkin's lymphoma should be considered in SLE patients who develop adenopathy or masses; lymphoma of the spleen is another cause of splenic enlargement in SLE
Systemic sclerosis (scleroderma)	Alveolar cell carcinoma Nonmelanoma skin cancer Adenocarcinoma of the esophagus	Pulmonary fibrosis, interstitial lung disease Areas of scleroderma and fibrosis in the skin Barrett's metaplasia	Annual chest radiograph after fibrosis is detected Change in skin features or poorly healing lesions should be evaluated If indicated, esophagoscopy and biopsy of distal esophageal constricting lesions
Dermatomyositis	Ovarian, lung, and gastric cancers in Western populations; nasopharyngeal carcinoma in Asian populations	Older, normal creatinine kinase levels, presence of cutaneous vasculitis; less likely in setting of myositis-specific antibodies	Malignancy evaluation needs to be tailored to individual patient's age, symptoms, and signs

Rheumatoid Arthritis

KEY POINTS

Rheumatoid arthritis is associated with a greater than twofold increased risk of lymphoma. This risk is higher in patients with high disease activity and with more severe disease, including extra-articular involvement.

The risk of solid malignancies is variable, with an increased risk of lung cancer and likely decreased risks of colorectal cancer, breast cancer, and cancers of the urogenital tract in men and women.

A link between lymphoma and rheumatoid arthritis was first reported from a medical record linkage study in 1978.⁹ Subsequently, a considerable body of evidence emerged supporting rheumatoid arthritis as a pathogenic factor in the development of lymphoma. A standardized incidence ratio (SIR) of 2.4 for lymphoma was described in a population of more than 20,000 Danish patients, as was an increased risk of 1.9 in 1852 U.S. patients.^{10,11}

Using a different approach, a pooled SIR of 3.9 for lymphoma was found using a random effects model in a meta-analysis.¹² Studies using other methods have found odds ratios of 1.3 to 1.5 for lymphoma in case-control studies.¹³

Patients with rheumatoid arthritis may be at higher risk for non-Hodgkin's lymphoma, especially diffuse large B cell type.¹⁴ Large B cell lymphomas represent up to two-thirds of non-Hodgkin's lymphomas in patients with rheumatoid arthritis^{6,8}—about twice the rate of diffuse large B cell lymphoma as a proportion of overall non-Hodgkin's lymphoma

in the general population. However, other studies have suggested that the immunophenotype, grade, and histology of lymphomas in patients with rheumatoid arthritis are not different from the general population.¹³

In many studies, the risk of cancer is particularly increased early in the disease course, and cancer risk appears to be greater in patients who have persistently high disease activity, high cumulative disease activity, and more severe disease, and in those who have positive rheumatoid factor (SIR, 3.6; 95% CI, 1.3 to 7.8).^{15,16} The unadjusted OR for average disease activity comparing highest versus lowest quartile was 71.3 (95% CI, 24.1 to 211.4), and the OR for cumulative disease activity of the 10th decile versus the 1st decile was 61.6 (95% CI, 21.0 to 181.0) in a case-control registry study from Sweden.¹⁶

Extra-articular disease of rheumatoid arthritis, particularly Felty's syndrome and Sjögren's syndrome, confers a further increased risk of non-Hodgkin's lymphoma; one study of 906 men with rheumatoid arthritis revealed a twofold increase in total cancer incidence among patients with rheumatoid arthritis who have Felty's syndrome.¹⁷ Large granular T cell leukemia (T-LGL) may rarely occur in association with rheumatoid arthritis.¹⁸ T-LGL in rheumatoid arthritis usually is chronic and rarely becomes aggressive.

Whether patients with rheumatoid arthritis are at higher risk for lymphoproliferative disorders other than lymphoma is unclear. At least one study from Canada noted an increased risk of leukemia with an SIR of 2.47 among patients with rheumatoid arthritis. It is interesting to note that an increased risk of lymphoma was not noted in this patient population.¹⁹ A U.S. Veterans Affairs study of 906 men with rheumatoid arthritis reported a twofold increased risk of overall cancer, although no single form of cancer

stood out, other than non-Hodgkin's lymphoma, for which a 12-fold increased risk was reported.¹⁷

A study that used statewide discharge records from California linking rheumatoid arthritis to Cancer Registry data for 1991 to 2002 revealed 5533 incident cancers among 84,075 rheumatoid arthritis patients observed for approximately 400,000 person-years.²⁰ As in other studies, the risk of developing lymphoproliferative cancers was significantly higher among both women and men with rheumatoid arthritis. Men had significantly higher risks for lung, liver, and esophageal cancers, although a lower risk for prostate cancer was noted. Females were at decreased risk for several cancers, including cancers of the breast, ovary, uterus, cervix, and melanoma, and risk reduction ranged from 15% to 57%, compared with the general population. In this study, Hispanic patients had increased risk of leukemia and vaginal/vulva, lung, and liver cancers.²⁰

The risk of premature death from leukemia and lymphoma in patients with rheumatoid arthritis has been reported to be similar or moderately increased compared with patients without rheumatoid arthritis.^{21,22} The rate per 100 patient deaths for leukemia/lymphoma is 1.78, including patients who have been treated with methotrexate and azathioprine.²²

A meta-analysis of 21 publications from 1990 to 2007 summarized the risk of malignancy in patients with rheumatoid arthritis.²³ The risk of lymphoma was increased approximately twofold (SIR, 2.08; 95% CI, 1.8 to 2.39), with greater risks of Hodgkin's and non-Hodgkin's lymphoma. The risk of lung cancer was increased with an SIR of 1.63 (95% CI, 1.43 to 1.87). The risk of colorectal cancer was decreased (SIR, 0.77; 95% CI, 0.65 to 0.90), as was the risk of breast cancer (SIR, 0.84; 95% CI, 0.79 to 0.90). The overall SIR for malignancy was slightly increased at 1.05 (95% CI, 1.01 to 1.09). The overall increased risk of cancer in patients with rheumatoid arthritis was largely driven by increased risks of lymphoproliferative cancers.

The risk of lung cancer was also higher among patients with rheumatoid arthritis in the U.S. veteran population. Patients with rheumatoid arthritis were 43% more likely (OR, 1.43) to develop lung cancer compared with patients without rheumatoid arthritis after adjustments for age, gender, race, and tobacco and asbestos exposure.²⁴ No effect of lung cancer on life expectancy was found in a retrospective cohort study; adenocarcinoma was the major histologic form of cancer found in patients with rheumatoid arthritis and in controls. Rheumatoid arthritis appeared to have no influence on the lung cancer stage.²⁵

A study of 42,262 patients hospitalized with rheumatoid arthritis from 1980 to 2004 indexed to the Swedish national cancer registry found that SIRs for Hodgkin's and non-Hodgkin's lymphoma were increased for upper digestive tract cancers and for squamous cell skin cancer, and detected an excess of nonthyroid endocrine tumors in patients with rheumatoid arthritis.²⁶ Colon and rectal and endometrial cancers were less frequent in patients with rheumatoid arthritis. The decreased risk of colorectal cancer may be attributable to the use of long-term nonsteroidal anti-inflammatory agents in patients with rheumatoid arthritis.²⁷

In summary, cancer is frequent in the general population and is at least as common among patients with rheumatoid

arthritis. Following a diagnosis of rheumatoid arthritis at the typical age of 55 years, one in five patients will be diagnosed with cancer; however, in the great majority of patients, the cancer cannot be linked to rheumatoid arthritis or to its treatment but rather reflects the background cancer risk. Although a history of previous lymphoma does not appear to be a risk factor for developing rheumatoid arthritis, risks of certain cancers, particularly hematopoietic malignancies, are increased and are related to the disease itself.⁷

Systemic Lupus Erythematosus

KEY POINTS

The risk of lymphoma is at least twofold increased in systemic lupus erythematosus (SLE).

Risks of solid malignancy, including lung, thyroid, and kidney cancers, and of skin cancer are increased overall in SLE, although rates of cervix and prostate cancers appear to be somewhat lower. Breast cancer risk has been reported to be increased in some studies and decreased in others.

The risk of at least certain malignancies appears to be increased in patients with SLE. Overall SIR ranges from 1.1 to 2.6,²⁸ with the most increased risk being that of lymphomas (SIR of 3.57 for non-Hodgkin's lymphoma and 2.35 for Hodgkin's disease).^{28,29} The risk is especially high for diffuse large B cell lymphoma, often of aggressive subtypes.^{30,31}

A large multicenter (23 centers) international cohort of 9547 patients with an average follow-up of 8 years confirmed an increased risk of cancer in patients with SLE. For all cancers combined, the SIR estimate was 1.15 (95% CI, 1.05 to 1.27); for all hematologic malignancies, it was 2.75 (95% CI, 2.13 to 3.49); and for non-Hodgkin's lymphoma, it was 3.65 (95% CI, 2.63 to 4.93). The data also suggest increased risks of lung cancer (SIR, 1.37; 95% CI, 1.05 to 1.76) and hepatobiliary cancer (SIR, 2.60; 95% CI, 1.25 to 4.78).²⁹

Patients with SLE in a California statewide patient hospital discharge database from 1991 to 2001 were followed using Cancer Registry data to compare observed versus expected numbers of cancers based on age, sex, and specific incidence rates in the California population.³² A total of 30,478 SLE patients were observed for 157,969 person-years. There were a total of 1,273 cancers for an overall significantly increased cancer risk (SIR, 1.14; 95% CI, 1.07 to 1.20). Patients with SLE had higher risks of vagina/vulva (SIR, 3.27; 95% CI, 2.41 to 4.31) and liver cancers (SIR, 2.70; 95% CI, 1.54 to 4.24). Also, elevated risks of lung, kidney, and thyroid cancers and hematopoietic malignancies were observed with lower rates of screenable cancers, including breast cancer, cervix cancer, and prostate cancer. Drug effects were not assessed.³²

Other studies have reported possibly increased risk of malignancies other than lymphoproliferative cancers in SLE. Patients may be at slightly higher risk of thyroid cancer.³³ An increased risk of squamous cell skin cancer was found in 238 patients with SLE.³⁴ The risk of breast cancer may be increased by about 1.5-fold to twofold compared with the general population, even after consideration of age,

parity, family history, and exogenous estrogens.^{28,35} The risk of abnormal Pap smears and cervical dysplasia appears to be higher in women with SLE than in those without SLE, although the risk of invasive cervical cancer is not increased.²⁹

The origin of any risk of the development of malignant disorders in SLE remains unclear, although it does not appear to be related to the use of immunosuppressive or cytotoxic agents; most cohorts are too small to allow detection of a statistically meaningful risk increase in rare events over short periods of observation. Race and ethnicity have not been identified as major factors in cancer risk in SLE.³⁶ Antimalarial drug use does not appear to affect the relative risk of malignancy, as was postulated in early studies.³⁷

Risk factors for the development of hematologic malignancies may relate to inflammatory burden and disease activity, immunologic defects and overexpression of *Bcl-2* oncogenes, and viruses, especially Epstein-Barr virus (EBV).³⁸ A nested case-control study that included 6438 patients with SLE linked to the national cancer registry in Sweden found that leukopenia, independent of immunosuppressive treatment, was a risk factor for developing these leukemias. Bone marrow investigation was suggested for SLE patients with long-standing leukopenia and anemia.³⁹ Disease characteristics predisposing to non-Hodgkin's lymphoma include longer disease duration and increased disease activity with moderately severe end-organ damage.⁴⁰

Women with SLE, likely out of concern for treatment side effects and effects of pregnancy on disease control, are less often exposed to oral contraceptives and are more likely to be nulliparous, which may affect their malignancy risk. On the other hand, the possibly increased breast cancer risk suggests that other, poorly understood factors may increase this risk in women with SLE, whereas at least one study suggested that patients with SLE are less likely than healthy women to undergo breast cancer screening.⁴¹ Patients with SLE also appear to be less likely to undergo routine Pap testing. Increased prevalence of human papillomavirus infection and immunosuppression have been implicated in the apparently increased prevalence of abnormal Pap smears and cervical dysplasia in patients with SLE.⁴²

Women with SLE may be at higher risk of lung cancer, for which smoking is a predictor.³⁸ Similar to rheumatoid arthritis, smoking is a risk factor for developing both SLE and lung cancer, reflecting a complex interplay of disease susceptibility factors.

Systemic Sclerosis (Scleroderma)

KEY POINTS

Risks of lymphoma, skin cancer, and lung cancer are markedly increased in scleroderma.

Scleroderma-related risk factors for malignancy include esophageal disease related to Barrett's esophagus and lung cancer related to pulmonary fibrosis.

The risk of malignancy in patients with scleroderma appears to be increased in most reviews and reports, although at least one population-based study failed to detect increased risk.^{43,44} Generally, estimates of malignancy risk in

scleroderma range from SIRs of 1.5 to 5.1, compared with the general population.^{45,46} The highest SIRs for individual cancers are those for lung cancer, with an incidence ratio of up to 7.8, and non-Hodgkin's lymphoma, with an incidence rate ratio (IRR) of 9.6.

A population-based disease registry and cancer registry retrospective cohort linkage study from Sweden following patients from 1965 to 1983 revealed an SIR of 1.5 for overall cancer, with highest rates for lung cancer (SIR, 4.9), skin cancer (SIR, 4.2), hepatoma (SIR, 3.3), and hematopoietic malignancies (SIR, 2.3).⁴⁵ A cohort study of patients followed from 1987 to 2002 revealed a similar magnitude of increased overall risk of malignancy (SIR, 1.55) with the observation of markedly increased risks of oropharyngeal cancer (SIR, 9.63; 95% CI, 2.97 to 16.3) and esophageal cancer (SIR, 15.9; 95% CI, 4.2 to 27.6).⁴⁵ Esophageal disease related to systemic sclerosis is the likely reason for the increased incidence of Barrett's esophagus, which has been reported to be present in 12.7% of patients with scleroderma.⁴⁶

A high rate of abnormal Pap tests in women with onset of scleroderma before the age of 50 has been reported, with a lifetime prevalence by self-report of 25.4% (95% CI, 20.9 to 30.4) compared with a self-reported prevalence of abnormal Pap tests in the general Canadian population of 13.8% (95% CI, 11.6 to 16.4). A significant relationship was found between self-reported abnormal Pap tests and diffuse disease and younger age at disease onset.⁴⁷

Lung cancer has been reported to account for up to 30% of all cancers in patients with scleroderma; it is thought to be related to fibrosis and, in several studies, not to smoking. The exact nature of the relationship is still unclear. A study of lung cancer occurring in scleroderma patients who were from a population with an already higher than expected rate of lung cancer revealed similar lung cancer rates in both cohorts. Another study from Australia suggested that patients who smoked were seven times more likely to develop lung cancer than those who did not smoke.⁴⁴ How the incidence rate of cancer in the referent population influences the estimation of rates of cancer in patients with scleroderma was also evident in a registry study from Detroit, in which an increased risk of cancer was not confirmed.^{44,48} This study included African-American females with scleroderma who appeared to have significantly higher rates of liver cancer (SIR, 45.8).⁴⁴

The mechanisms of malignancy in scleroderma are largely unexplored. Mechanisms likely vary by individual patient susceptibility and by cancer type and disease-specific factors. Risk factors for development of malignancy in patients with scleroderma may be related to inflammation and fibrosis of affected organs. The link to smoking is controversial.^{44,48} As in some other autoimmune rheumatic diseases, the risk appears higher early in the disease, and patients who are older at the time of diagnosis may be at higher risk as well.^{45,49} It is not certain whether the presence of scleroderma-specific antibodies, particularly topoisomerase I (Scl-70), defines an increased risk for development of cancer in these patients.^{43,49} RNA polymerase I/III autoantibody response in malignancy may initiate the scleroderma-specific immune response and drive disease in a subset of scleroderma patients.⁵⁰ In contrast to systemic sclerosis, localized scleroderma, including morphea and linear

scleroderma, has not been associated with increased risk of cancer.⁵¹

Idiopathic Inflammatory Myopathy

KEY POINTS

The risk of cancer in patients with idiopathic inflammatory myopathies is about five to seven times higher than in the general population.

Malignancy is strongly associated with dermatomyositis and, if present, is often detectable at disease outset.

The most common malignancies in inflammatory myositis are adenocarcinomas.

Suspicion for cancer should be high, especially in patients with active muscle and skin inflammation but normal creatine kinase levels, age over 50 years, and periungual erythema.

Both dermatomyositis and polymyositis occurring in adults have been associated with malignancies. The link to malignancy in newly diagnosed patients with dermatomyositis is strongest, although in neither condition is the origin of the association well understood. The association between malignancy and polymyositis and inclusion body myositis is less strong.

Assessment of risk is complicated by the temporal relationship between the development of malignancy and cancer. In particular, some cancers pre-date the onset of inflammatory myopathy, so that the inflammatory myopathy can be better considered a paraneoplastic syndrome (see Chapter 122); it is also likely that the presence of inflammatory myopathies represents a risk factor for the subsequent development of malignancy.⁵²

The incidence of cancer occurring in patients with inflammatory myositis is approximately five to seven times higher than in the general population.⁵³ The prevalence of malignancy is about 25%; cancers are reported more frequently in dermatomyositis, occurring in 6% to 60% of patients, and in 0 to 28% of patients with polymyositis.⁵⁴

In most studies, cancers manifest within 2 years before or after the initial diagnosis of inflammatory myopathy.^{55,56} Inflammatory myopathies may initially manifest with the recurrence of a previously diagnosed cancer. A previously diagnosed but inactive inflammatory myopathy may become reactivated with occurrence of a cancer, supporting the hypothesis of autoantigens as drivers of the inflammatory disease.

The strength of the association between malignancy and inflammatory myositis varies. One study done at the Mayo Clinic failed to reveal an increased risk of malignancy in patients with inflammatory myopathy, and a more recent registry study from Sweden of 788 patients diagnosed with dermatomyositis or polymyositis between 1963 and 1987 revealed that 15% of 392 patients with dermatomyositis had cancer diagnosed concurrently with or after the diagnosis of dermatomyositis, with a relative risk of cancer of 2.4 (95% CI, 1.6 to 3.6) for males and 3.4 (95% CI, 2.4 to 4.7) for females.^{52,55} Of 396 patients with polymyositis, 9% had cancer at or after the time of diagnosis of polymyositis, with

the relative risk of 1.8 for development of cancer (95% CI, 1.1 to 2.7) in males and 1.7 (95% CI, 1.0 to 2.5) in females.

A population-based retrospective cohort study from Victoria, Australia, of 537 patients with biopsy-proven dermatomyositis and polymyositis reported a relative risk for malignancy in dermatomyositis compared with polymyositis of 2.4 (95% CI, 1.3 to 4.2) with a higher SIR for dermatomyositis than polymyositis (6.2 vs. 2.0).⁵⁶ Finally, odds ratios for association of cancer with dermatomyositis from a large meta-analysis were reported to be 4.4, and for polymyositis, 2.1.⁵⁷

A wide range of malignancies are associated with dermatomyositis and polymyositis. The most common malignancies in populations of Northern European descent are adenocarcinomas of the cervix, lungs, ovaries, pancreas, bladder, and stomach, which account for more than two-thirds of these cancers.^{58,59} In patients from Southeast Asia, a higher proportion of nasopharyngeal cancers are found, followed by lung cancer.⁵⁸

The association of cancer is less well understood for more unusual forms of inflammatory myopathies. Amyopathic dermatomyositis, a rare form of dermatomyositis with typical cutaneous but no muscle involvement, can be associated with the development of cancer, but the frequency of this condition is low, so that no stable estimates of cancer risk are available.⁵⁹ Inclusion body myositis has not been well studied for the same reasons, although the overall risk of cancer of 2.4 suggests a possible link.⁵⁶

It is likely that relevant antigens are expressed in the underlying tumor and affected muscle. Myositis-specific antigens develop during the process of regeneration in patients who have myositis; these are the same antigens expressed in some cancers known to be associated with the development of inflammatory myopathies.⁶⁰ A link between malignancy and inflammatory myositis is further supported by observations that in many cases, myositis improves after removal of the malignancy.⁶¹

Clinical disease characteristics that may portend higher malignancy risk include active inflammatory disease with normal serum levels of creatine kinase, distal extremity weakness, pharyngeal and diaphragmatic involvement, and leukocytoclastic vasculitis.⁶²⁻⁶⁴ Other independent risk factors for the development of cancer in patients who have dermatomyositis in one study of 92 patients included age at diagnosis greater than 52 years (hazard ratio [HR], 7.24; 95% CI, 2.35 to 22.41), rapid onset of skin and/or muscle symptoms (HR, 3.11; 95% CI, 1.07 to 9.02), periungual erythema (HR, 3.93; 95% CI, 1.16 to 13.24), low baseline level of complement factor C4 (HR, 2.74; 95% CI, 1.11 to 6.75), and possibly topoisomerase I.^{65,66} A low baseline lymphocyte count was a protective factor for malignancy (HR, 0.33; 95% CI, 0.14 to 0.80), although the number of assessable patients was small.⁶⁵

Sjögren's Syndrome

KEY POINTS

The risk of lymphoproliferative cancers, especially various types of lymphoma, is at least sixfold increased in patients with primary Sjögren's syndrome.

Immunologic perturbations, including p35 mutations and B cell activation, as well as *Helicobacter pylori*, are likely predisposing risk factors.

Patients with primary Sjögren's syndrome are at increased risk of lymphoproliferative diseases, especially non-Hodgkin's lymphoma. The relative risk for the development of lymphoproliferative disorders in these patients ranges from 6 to 44 in individual studies, and a meta-analysis of cohort studies reported a pooled SIR of 18.8.⁶⁷ Lymphoproliferative disorders eventually occur in between 4% and 10% of patients with primary Sjögren's syndrome, with a lifetime risk of non-Hodgkin's lymphoma of about 5%.^{11,67-71}

In addition to non-Hodgkin's lymphoma, forms of lymphoproliferative disease seen in patients with Sjögren's syndrome include low-grade B cell lymphoma and diffuse large B cell lymphoma, including follicular center lymphoma. Less commonly seen lymphoproliferative diseases include lymphocytic leukemia, Waldenström's macroglobulinemia, and multiple myeloma.⁶⁹ The risk of other cancers does not appear to be particularly high in patients with Sjögren's syndrome.⁶⁹⁻⁷¹ The development of lymphoma and malignancy in patients with Sjögren's syndrome does not appear to affect or cause mortality.^{11,71}

The pathoetiology of lymphoproliferative diseases occurring in patients with Sjögren's syndrome is unclear. It is likely that the B cell activation characteristic of Sjögren's syndrome is a predisposing risk factor. Most lymphomas in Sjögren's syndrome appear to arise from lymphoepithelial sialadenitis or benign lymphoepithelial lesions, perhaps associated with p35 mutations.⁷² Infectious agents such as hepatitis C and Epstein-Barr virus have been implicated, although the nature of this relationship remains speculative. *Helicobacter pylori* is associated with MALT (mucosa-associated lymphoid tissue) lymphoma in Sjögren's syndrome.⁷³

Appropriate evaluation in symptomatic patients should include diagnostic testing for *H. pylori* in this setting.⁷⁴ The link of cancer in Sjögren's syndrome to the proto-oncogene *Bcl-2* translocation is, as yet, not clearly defined but may be helpful for early detection of malignancy.^{75,76}

Vasculitis

KEY POINT

It is unclear whether the risk of cancer development is increased in vasculitis independent of drug treatment effects.

Vasculitis as a paraneoplastic syndrome may be present in about 8% of patients with malignancy (see Chapter 122).⁷⁷ Not as well studied is the risk of primary malignancy in patients with vasculitis. Most cases appear to be related to treatment, although one study using the Danish Cancer Registry suggested an increased risk of nonmelanoma within 2 years of the vasculitis diagnosis in antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (granulomatosis with polyangiitis [formerly Wegener's granulomatosis]) (OR, 4.0; 95% CI, 1.4 to 12).⁷⁸

Current data do not support a link between ANCA-associated vasculitis (granulomatosis with polyangiitis) and malignancy as a trigger for vasculitis, or the vasculitis itself as a trigger for malignancy, independent of treatment effects.

The risk of malignancy among patients with giant cell arteritis was not increased in a population-based study of 204 patients with giant cell arteritis and 407 age- and sex-matched controls.⁷⁹

Seronegative Spondyloarthritis

KEY POINT

The overall risk of cancer does not appear to be increased in the seronegative spondyloarthropathies.

The risk of cancer among patients with spondyloarthropathies is not as well studied as that of patients with rheumatoid arthritis and other connective tissue diseases. A cohort study of 665 patients from Canada with psoriatic arthritis revealed an SIR for all cancers of 0.98 (95% CI, 0.77 to 1.24) without evidence of increase in cancer type-specific SIR for hematologic, lung, or breast cancer.⁸⁰

No overall increased risk of cancer has been noted among patients with ankylosing spondylitis, as was reported in a Swedish national cohort of patients with ankylosing spondylitis admitted to Swedish hospitals from 1965 to 1995, linked to the Swedish Cancer Registry and Death Registry. These patients appear to not have increased risk of malignant lymphoma.^{81,82} A population-based cohort study of patients with ankylosing spondylitis from Australia suggests a prevalence of malignancy of 6.8%, which parallels baseline population prevalence rates reported in Western populations.⁸³

CANCER RISKS ASSOCIATED WITH ANTIRHEUMATIC DRUG THERAPIES

KEY POINTS

The effect on cancer risk of therapies used in the treatment of autoimmune rheumatic diseases can be difficult to separate from the underlying risk intrinsic to the diseases themselves.

Nonsteroidal anti-inflammatory drugs and glucocorticosteroids have not been associated with increased risk of cancer.

The risk of cancer with chemotherapeutic drugs is greatest in patients who have had the highest cumulative exposure to these agents.

Assessment of risk associated with both nonbiologic and biologic DMARDs is challenging because of the overall generally high burden of cancer in the population, the variable rheumatic disease-related cancer risk, and the potential risk of cancer associated with agents used to treat them. Disease severity may be a risk factor for developing cancer, introducing confounding or channeling bias if patients with

severe disease are treated more intensively with immunomodulatory agents. The sequential and combined use of immunomodulatory agents further complicates the assessment of risk related to individual agents. A further concern, as with all immunosuppressive drugs, is the oncogenic potential of immunosuppressive therapies in patients who have a pre-existent or concurrent cancer, and whether such patients should be treated with DMARDs, and if so, which DMARDs should be given.

Nonsteroidal anti-inflammatory agents and glucocorticosteroids do not appear to be associated with increased risk of malignancy in patients with rheumatoid arthritis nor other rheumatic diseases.^{84,85} In a large population-based cohort study from Sweden, a total duration of oral steroid treatment of less than 2 years was not associated with lymphoma risk (OR, 0.87; 95% CI, 0.51 to 1.5), whereas treatment lasting longer than 2 years was associated with a lower lymphoma risk (OR, 0.43; 95% CI, 0.26 to 0.72).⁸⁶ The duration of rheumatoid arthritis at initiation of oral corticosteroids did not affect lymphoma risk. Whether this observed reduced lymphoma risk may be due to decreased disease activity, is a generic effect of steroids, or is specific to rheumatoid arthritis is uncertain.⁸⁶

Nonbiologic Disease-Modifying Antirheumatic Drug Therapy

KEY POINTS

The nonbiologic disease-modifying antirheumatic drugs gold, hydroxychloroquine, penicillamine, and sulfasalazine are not associated with increased risk of cancer.

The risk of lymphoma, especially B cell lymphoma, may be increased with methotrexate. Some patients may experience regression with discontinuation of methotrexate.

Use of azathioprine is associated with increased risk of lymphoma, and alkylating agents are particularly associated with increased risk of several types of malignancies, including bladder and lung cancer and leukemia in patients treated with cyclophosphamide.

The nonbiologic (nb-)DMARDs sulfasalazine and hydroxychloroquine and gold and penicillamine do not appear to be associated with increased risk of cancer. Radiation is no longer used for the treatment of rheumatic diseases and will not be further addressed. Although no increase in cancer occurrence has been reported, a paucity of data is available regarding the long-term risks of malignancies occurring with leflunomide.⁸⁷

All of the antimetabolites used in prevention of transplant rejection and treatment of cancer have tumorigenic potential and, in general, may, or do, confer an increased risk of malignancy. The risk of cancer is increased with chemotherapeutic nb-DMARDs, particularly cyclophosphamide, and the risk of certain cancers, particularly lymphoproliferative disorders, may be increased with the use of other nb-DMARDs, such as azathioprine, methotrexate, and cyclosporine, although data are relatively sparse. Data regarding cancer risk in rheumatic diseases in patients treated with mycophenolate mofetil are few, although cancers clearly do occur in patients treated with this drug.⁸⁸

Overall risk for lymphoproliferative disorders in patients treated with nb-DMARDs appears to be greatest in patients who have had highest cumulative exposure to DMARDs, compared with patients with less than 1 year of exposure (SIR, 4.82).⁸⁹ A case-control study of 378 Swedish patients with rheumatoid arthritis who developed lymphoma and controls demonstrated that high accumulated rheumatoid arthritis disease activity was associated with increased lymphoma risk (relative risk [RR] of 62 for highest vs. lowest deciles of accumulated disease activity; 95% CI, 21 to 181). When adjusted for disease activity, DMARD use did not emerge as a risk factor (RR, 0.9; 95% CI, 0.6 to 1.2), with the exception of azathioprine, which was associated with a fourfold increased risk of lymphoma.⁸⁴

Methotrexate

The overall malignancy risk attributable to methotrexate treatment in patients with rheumatic diseases does not appear to be increased, although numerous studies suggest that the risk of lymphoproliferative disease may be increased.

Most cases of methotrexate-associated lymphomas reported in the literature are B cell lymphomas, often with extranodal involvement.⁹⁰ Assays for EBV in one study revealed that 7 of 17 patients (41%) were positive.⁹⁰ Further evidence supporting a link between methotrexate use and the development of lymphoma comes from observations of spontaneous remission of B cell lymphoma in 8 of 50 cases, including 4 that were positive for EBV.⁹⁰ This suggests that methotrexate may potentiate persistent immunologic stimulation, clonal selection, and malignant transformation of B cells by direct oncogenic action, decreased apoptosis of infected B cells, and decreased natural killer cell activity.⁹⁰

Azathioprine

The use of azathioprine may be associated with increased risk of lymphoproliferative disorders. Studies from a Canadian azathioprine registry revealed increased rates of lymphoproliferative disorders in patients with rheumatoid arthritis compared with the general population (SIR, 8.05).⁹¹ A study from Britain also revealed a markedly increased risk of development of lymphoma in rheumatoid arthritis patients treated with azathioprine, with an estimated 1 case of lymphoma per 1000 patient-years of azathioprine treatment.⁹² Risk was highest in patients on higher daily doses of azathioprine of up to 300 mg per day.

The risk of leukemia in patients with systemic lupus erythematosus treated with azathioprine has been generally reported as not increased, although at least one study reported an increase in risk.⁹¹⁻⁹³ In one study with up to 24 years of longitudinal follow-up, 5.4% of patients treated with azathioprine developed malignancies, none of which were lymphomas, compared with 6.7% of patients who had never received azathioprine, 3 of whom developed lymphoma.⁹³

Cyclosporine

Relatively few patients with rheumatic diseases treated with cyclosporine have been followed for protracted periods,

making assessment of malignancy risk in these patients difficult. Similar to methotrexate, cyclosporine has been associated with the development of EBV-associated lymphomas in a few patients with rheumatoid arthritis.⁹⁴ A retrospective study aggregating experience from clinical trials of more than 1000 patients with rheumatoid arthritis treated with cyclosporine failed to demonstrate an increased risk of malignancy, at least beyond that seen with other DMARDs.⁹⁵

Alkylating Agents

The use of alkylating agents in patients with rheumatoid arthritis, systemic lupus erythematosus, and vasculitis has been associated with an increase in non-Hodgkin's lymphoma, leukemia, skin cancer, bladder cancer, and solid malignancies.⁹⁶⁻⁹⁸ Considerably more experience with cyclophosphamide than chlorambucil has been documented in these diseases.

Cyclophosphamide use in rheumatic diseases is associated with an overall increased risk of developing malignancy of between 1.5 and 4.1, compared with controls. This risk is best studied in ANCA-associated vasculitis (especially necrotizing granulomatosis with polyangiitis), in which risk is highest for bladder cancers (SIR, 4.8), leukemia (SIR, 5.7), and lymphoma (SIR, 4.2). Bladder cancer is a particular concern, and patients who have been treated with higher doses over longer periods and those who smoke appear to be at especially high risk.⁹⁷ Bladder cancer related to cyclophosphamide use may occur within 1 year of initiation of therapy and up to 15 years or longer after discontinuation of cyclophosphamide treatment.⁹⁷

Increased risk of hemorrhagic cystitis of the urinary bladder or development of bladder cancer is due to cyclophosphamide metabolites, especially acrolein. For this reason, current recommendations are to attempt to restrict the use of cyclophosphamide to 6 months or less, and to use it only in life-threatening or organ-threatening disease. The risk of bladder cancer, although probably not the overall malignancy risk, may be less with the use of pulse intravenous cyclophosphamide than with daily oral administration. Some authors advocate concurrent administration of mesna, which inactivates acrolein in the urine. Mesna may be administered intravenously at the time of pulse cyclophosphamide dosing, or by mouth daily, although this is rarely done because of its disagreeable taste.

Biologic Response Modifiers

KEY POINTS

The overall risk of cancer associated with biologics used in the treatment of rheumatoid arthritis does not appear to be markedly increased from baseline cancer risk in these patients.

The risk of skin cancer, especially nonmelanotic skin cancer, does appear to be somewhat increased by about 1.5-fold in patients treated with anti-tumor necrosis factor therapy.

Biologic response modifiers target specific pathways involved in the pathogenesis of some rheumatic diseases such as rheumatoid arthritis and spondyloarthritis. The term *targeted* should not imply absolute selectivity between physiologic and pathologic processes with these drugs.

Anti-Tumor Necrosis Factor Agents

More than 40 randomized controlled trials and several large cohort studies have investigated the use of anti-tumor necrosis factor (TNF) agents over a wide range of indications. Table 37-2 contains a list of meta-analyses and cohort studies undertaken to explore anti-TNF treatment and solid cancer/lymphoma in rheumatoid arthritis. The concern regarding cancer arises from animal models of TNF action, in vitro studies, and studies in humans suggesting that TNF is important in cancer initiation and promotion; indeed, anti-TNF agents may even be beneficial for patients with cancers, although clinical evidence of such a benefit is lacking.⁹⁹ An interesting observation of regression of non-small cell lung cancer in a patient receiving anti-TNF therapy has been reported, which adds to the biologic plausibility of a connection between anti-TNF therapies and malignancy in individual patients who may have particular susceptibility.¹⁰⁰

A report from a large U.S. databank about malignancies in patients with rheumatoid arthritis treated with anti-TNF therapies and followed for more than 10,000 patient-years compared with all patients with rheumatoid arthritis regardless of therapy followed for more than 29,000 patient-years reported an SIR for lymphoma of 2.9 in those patients receiving anti-TNF compared with 1.9 for all rheumatoid

Table 37-2 Meta-analyses and Cohort Studies Exploring Anti-Tumor Necrosis Factor Treatment and Solid Cancer/Lymphoma in Rheumatoid Arthritis

References	Study Design	Number of Patients	Risk Estimate (All Anti-TNF* vs. Control Unless Stated Otherwise)
103	RCT meta-analysis	5014	OR, 3.3 (95% CI, 1.2 to 9.1)
104	RCT meta-analysis	5788	OR, 2.4 (95% CI, 1.2 to 4.8)
101	Cohort (NDB)	13,869	OR, 1.0 (95% CI, 0.8 to 1.2)

105	RCT meta-analysis	8808	OR, 1.31 (95% CI, 0.69 to 2.48) OR, 1.21 (95% CI, 0.63 to 2.32) "Exposure adjusted" NMSC excluded
106	Cohort SBR	6366	RR, 1.00 (95% CI, 0.86 to 1.15) NMSC excluded
108	Nested case-control (RABBIT)	Cases: 74; cohort overall 5120	No difference in anti-TNF exposure

*Etanercept, infliximab, and adalimumab account for the vast majority (>90%) of anti-TNF agents in these studies.

CI, confidence interval; HR, hazard ratio; NDB, National Databank for Rheumatic Diseases; NMSC, nonmelanotic skin cancer; OR, odds ratio; RABBIT, German Biologic Register; RCT, randomized controlled trial; RR, relative risk; SBR, Swedish Biologics Register; TNF, tumor necrosis factor.

arthritis patients, regardless of therapy.¹⁰¹ A biologics registry study from Sweden found an SIR of 2.9 for lymphoma compared with the general population, but when compared with TNF-naïve patients, the risk was not elevated (RR, 1.1).¹⁰²

The possibly increased risk of cancer early after the start of anti-TNF therapy may be a factor in meta-analyses of randomized clinical trials, which have suggested a possibly increased risk of cancer in patients with rheumatoid arthritis treated with these agents. One meta-analysis of nine randomized clinical trials including infliximab and adalimumab found an odds ratio of 2.4 for developing any malignancy for patients receiving infliximab or adalimumab compared with patients receiving placebo.¹⁰³

Another analysis based on individual patient data from all nine available randomized etanercept trials in patients with rheumatoid arthritis included 3316 patients, 2244 of whom received etanercept and 1072 who were TNF naïve. Incident malignancies were diagnosed in 26 patients in the etanercept group and 7 patients in the control group, yielding a hazard ratio of 1.84 (95% CI, 0.79 to 4.28).¹⁰⁴

A pooled analysis of randomized controlled trials using etanercept, infliximab, or adalimumab attempted to distinguish between the effects of recommended versus higher doses of anti-TNF on the development of malignancy, excluding nonmelanoma skin cancers. Exposure-adjusted analysis revealed odds ratios of 1.21 (95% CI, 0.79 to 4.28) and 3.04 (95% CI, 0.05 to 9.68) in patients treated with recommended and high doses of anti-TNF agents, respectively.¹⁰⁵

Results of larger observational studies have not replicated the increased risk of malignancy observed with meta-analytical approaches. In the Swedish Biologics Registry, overall cancer risk was similar in anti-TNF-treated patients with rheumatoid arthritis compared with three different control cohorts.¹⁰⁶ In this database, no trend toward increased cancer incidence was noted with longer duration of TNF exposures. Studies from other databases including the German and British Biologic Registries and a large North American cohort have detected no significant safety signals with respect to overall cancer risk.^{101,107-109}

Use of anti-TNF agents may be associated with increased risk of nonmelanotic skin cancer. An odds ratio for non-melanotic skin cancer of 1.5 (95% CI, 1.2 to 1.8) was reported from the U.S. National Databank of Rheumatic Diseases.¹⁰¹ A cohort study from this population suggested that the combination of TNF plus methotrexate versus control was associated with a higher risk of nonmelanoma skin cancer (HR, 1.97; 95% CI, 1.51 to 2.58) compared with a hazard ratio of 1.24 (95% CI, 0.97 to 1.58) in patients receiving anti-TNF monotherapy versus controls, emphasizing the possible potentiating effects of combination therapies for the development of cancers. This point is perhaps underlined by observations from a randomized clinical trial of 180 patients with ANCA-associated (granulomatosis with polyangiitis) vasculitis. The occurrence of solid and skin malignancies in the group assigned to etanercept was increased above that expected from treatment with cyclophosphamide alone.¹¹⁰

Discordant results regarding cancer risk are likely explained by different patient populations and differing drug exposures. Meta-analyses of clinical trials generally

reflect relatively short-term effects but offer the advantage of randomization, which should largely neutralize the variability introduced by individual comorbidities and previous drug exposures; long-term observational studies place more emphasis on mid- and long-term results. In either case, if cancer events occur in a nonlinear fashion with early dropout of individuals at risk for cancer, a conclusive analysis, even after several years of follow-up, may be unable to capture such a signal.

A crucial clinical question is whether patients with pre-existent cancers should be exposed to anti-TNF or other immunomodulatory therapies. Patients with pre-existent malignancies are generally excluded from clinical trials, and in clinical practice, clinicians may be reluctant to treat such patients with anti-TNF therapy, resulting in channeling of treatment with these agents toward low-risk cohorts. An analysis from the British Biologics Registry detected no increased risk of recurrent cancer in patients with pre-existing malignancy (IRR, 0.53; 95% CI, 0.22 to 1.26).¹⁰⁹ Also, data from the German Biologic Registry reveal no significantly increased risk of recurrence in patients with a previous malignancy treated with anti-TNF agents (IRR, 1.4; 95% CI, 0.5 to 5.5).¹⁰⁶ However, very few events were included in these analyses, so definite conclusions about overall or cancer-specific risks in individual patients cannot be drawn.

Rituximab

B cells appear to be involved in generation of antitumor responses and are important in maintaining inflammatory states, which promote carcinogenesis and tumor growth.¹¹¹ The absence of B cells, for example, in hypogammaglobulinemia, has not been associated with increased susceptibility to cancers, and B cell depletion with rituximab has been shown to slow the growth of solid nonhematopoietic murine tumors.¹¹²

Pooled analysis of safety data from patients with rheumatoid arthritis treated with rituximab in randomized controlled trials with more than 5000 patient-years of exposure revealed an incidence of malignancy excluding nonmelanoma skin cancer of 0.84 per 1000 patient-years (SIR, 1.05; 95% CI, 0.76 to 1.42).¹¹³ The incidence appeared to be stable over multiple courses of rituximab, and no unusual pattern of malignancy type was observed.

Abatacept

Abatacept is a fusion protein consisting of the extracellular domain of human cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) linked to the Fc portion of human immunoglobulin. CTLA-4-mediated T cell suppression has been suggested to be important in the pathogenesis of several types of malignancies, especially malignant melanoma.¹¹⁴ Because abatacept blocks the same signal that new anticancer treatments based on this interaction are intended to enhance, theoretically a potentially increased risk of malignancies may be seen with the use of this biologic. So far, however, no signal for increased malignancies has been noted in patients treated with this agent.¹¹⁵ However, as with other contemporary trials, the abatacept trials in rheumatoid arthritis have excluded patients with a history of

cancer, and some studies have required negative screening mammograms before administration.

Tocilizumab

Tocilizumab is a humanized monoclonal antibody to the interleukin (IL)-6 receptor. IL-6 has an important role in inflammation and in the promotion of various types of malignancies, including suppression of apoptosis, promotion of angiogenesis, and induction of genes that mediate cell proliferation.¹¹⁶ IL-6 antagonists have been used in advanced multiple myeloma, with some evidence of efficacy.¹¹⁷

Data from studies of rheumatoid arthritis, the disease in which experience with this agent is most extensive, so far have not revealed any signals of an increased incidence of cancer during the 6-month controlled period of randomized clinical trials or follow-up. Labeling information for tocilizumab contains a general statement that “treatment with immunosuppressants may result in an increased risk of cancer,” but no specific warnings are included.

Anakinra

The IL-1 receptor antagonist, anakinra, has been best studied in rheumatoid arthritis. As is the case for most studies of biologic response modifiers, methotrexate usually has been administered concomitantly. The case rate for the development of malignant lymphoma with anakinra is 0.12 cases per 100 patient-years, with 8 cases of lymphoma observed among 5300 patients with rheumatoid arthritis treated with this drug in clinical trials for a mean of 15 months.¹¹⁸ This represents a 3.6-fold higher than expected rate of lymphoma compared with the general population. The SIR for lymphoma in this study (3.71; 95% CI, 0.77 to 11.0) is consistent with odds ratios from other studies of patients with rheumatoid arthritis. A number of solid tumors have also been reported with this agent. Whether anakinra is carcinogenic is unclear but cannot be excluded.¹¹⁸ The overall incidence of malignancies with anakinra use in rheumatoid arthritis is consistent with expected rates reported in the U.S. National Cancer Database.

Cancer Screening in Patients with Rheumatic Disease

Evidence of cancer risk in patients with rheumatic diseases forms the basis for clinically useful recommendations regarding cancer screening. First, with respect to management of the inflammatory disease, it is imperative to achieve optimal disease control and the lowest level of clinical disease activity possible using the least intensive treatment regimen available. Second, patients for whom immunomodulatory therapy including nb-DMARDs and biologic DMARDs is being contemplated should undergo routine cancer screening that is appropriate to their age, sex, familial cancer burden, and risk factors such as smoking. Third, because cancers may develop at an accelerated rate in the first few months to the first year or so of treatment, patients should be seen at frequent intervals and closely questioned and examined for signs and symptoms of malignancy, especially during this initial treatment period, and throughout the course of their disease.

Routine blood counts and differential blood cell counts should be performed at the initiation of treatment and as appropriate for the specific drug therapy used. Age- and gender-appropriate cancer screening for colorectal cancer, prostate cancer, breast cancer, and cervical cancer is advisable. In patients with particularly high cancer risk, such as dermatomyositis, assessment for tumor markers such as CA-125 and radiographic imaging of chest, abdomen, and pelvis may be appropriate yearly in the first year or two of the disease, and then as otherwise clinically indicated.¹¹⁹

Especially patients taking alkylating agents such as cyclophosphamide may be at particularly high risk of cancer. These patients certainly should undergo routine cancer screening Pap smears and urinalyses for at least 15 years from cyclophosphamide therapy. With these considerations, the morbidity and mortality experienced by patients with rheumatic disease can be favorably managed.

CONCLUSION

Assessment of risk for malignancy in patients with rheumatic diseases is complex. Some rheumatic diseases such as dermatomyositis and Sjögren's syndrome appear to confer a particularly high risk of cancers, particularly lymphoproliferative disorders. Many of these diseases are relatively rare, so that large patient cohorts required for more precise assessment of risk are not available or must be studied over long periods of time to develop stable risk estimates.

Malignancy and perineoplastic syndrome should be considered when patients present with musculoskeletal symptoms caused by an underlying malignancy, or noted as symptoms and signs associated with the presence of an underlying malignancy in a patient with a pre-existent autoimmune disease.

Most of the agents used in the treatment of these diseases are purposefully employed to modulate the immune response, and some, including the alkylating agents, are known carcinogenics. Others may modulate immune response to decrease tumor surveillance. Further complicating the assessment are the individual susceptibility host factors, including the presence of oncogenic genes such as *Bcl-2*, and family history and environmental factors such as viruses, which may enhance the carcinogenic potential of the treatments.

Recommendations for treatment must include a general understanding of the disease and treatment-related malignancy and individualized discussion with the patient regarding risks and benefits of treatment as they relate to disease activity and severity and, most important, patient preference.

KEY POINTS

The aims of rehabilitation are to maximize function and minimize activity limitation and participation restriction.

The International Classification of Functioning, Disability and Health (ICF) provides the common framework for rehabilitation.

Modern rehabilitation is interdisciplinary using a patient-centered approach.

The main focus in the assessment and treatment of patients is on function.

Exercise is consistently effective in the treatment of various rheumatic diseases.

Physical modalities may be used as an adjunct to active therapies.

Rehabilitation includes not only the training of disabled individuals, but also intervention in the adaptation of the environment.

Rehabilitation is a specialized medical field that combines medical therapy and nonpharmacologic interventions with the goals of maximizing function and independence and ameliorating symptoms. The rehabilitation community has embraced the International Classification of Functioning, Disability, and Health (ICF)¹ as a framework for developing interventions to address the consequences of disease, communicating about strategies that enable individuals to engage fully in society, and formulating research in rehabilitation medicine.²⁻⁷

Rehabilitation interventions are multimodal and diverse and are designed to help individuals with arthritis live with their disease.⁸⁻¹⁵ Exercise is the most studied and best proven intervention.¹⁵⁻¹⁷ Physical modalities such as ultrasound and heat are adjuncts to exercise and show modest benefits with respect to pain relief, extensibility of tissue, and relaxation.^{8-10,13-15} Orthotics, ambulatory devices, splints, and adaptive devices enable patients to navigate barriers that persist despite other interventions.¹⁸⁻²⁰

The design of rehabilitation programs is based on the disease state, the severity of disease, the use and type of medications, and social, psychological, and environmental factors. This chapter provides an introduction to physical medicine and rehabilitation with an emphasis on nonpharmacologic interventions. Key principles of rehabilitation will be discussed, and management strategies for specific arthritic conditions will be highlighted.

Introduction to Physical Medicine, Physical Therapy, and Rehabilitation

MAURA DALY IVERSEN

BRIEF HISTORY OF REHABILITATION IN ARTHRITIS

Early arthritis rehabilitation focused on bed rest, splinting, and gentle range-of-motion exercises. Physicians and rehabilitation specialists believed that physical activity and strenuous exercise would produce pain, increase joint swelling and temperature, and accelerate joint damage. In the 1940s, with the introduction of steroids, highly efficient and potent anti-inflammatory drugs, the rehabilitation focus shifted toward splinting and mobilizing patients with assistive devices to promote function. Surgical approaches such as joint replacements were used in the 1960s and 1970s to “stop” the progression of disease. At this time, rehabilitation interventions focused on postoperative protocols to enable patients to regain function and maximize independence. Through the 1970s and 1980s, with the proliferation of disease-remitting agents such as myochrysine, methotrexate, and sulfasalazine, rehabilitation regimens began to incorporate dynamic exercises and functional activities earlier in the disease process. Rehabilitation researchers also began to evaluate the impact of isometric and low-intensity isotonic exercise on immune response and function. Early data from these trials suggested positive effects on disease activity and strength.^{21,22} As more medications entered the market and the prevalence of disease-modifying antirheumatic drugs (DMARDs) in clinical practice expanded, rehabilitation research focused on evaluation of the effects of various intensities, frequencies, and modes of strengthening exercises on patient outcomes. From the mid-1990s onward, studies of aerobic exercise illuminated the benefits of aerobic conditioning for cardiovascular function without deleterious effects on joints and soft tissue.²³⁻²⁵ In the 21st century, with the development of advanced radiologic techniques and the advent of biologic therapies, researchers are investigating the impact of weight-bearing activities on joint integrity in people with arthritis²⁶ and are embracing a public health perspective through promotion of community physical activity programs designed to improve quality of life and function.^{27,28}

GOALS OF REHABILITATION, REHABILITATION TEAM MEMBERS, AND MODELS OF TEAM CARE

Rehabilitation interventions address all aspects of the patient’s condition with the aim of maximizing function and

independence. As such, interventions range from prescription of adaptive devices, such as splints, orthotics, and ambulatory devices, to use of physical modalities, such as ultrasound, heat, and cold, to instruction in exercise and self-management strategies (relaxation, proper rest). Rehabilitation specialists are educated to assess environmental factors so they can best address barriers and facilitators impacting their patients.²⁹

The initial phase of the rehabilitation process involves a comprehensive assessment of all dimensions of the patient's life and condition. Given the fluctuating course of many arthritides, a coordinated effort by a variety of skilled multiprofessional rehabilitation specialists is required. The structure, function, and resources of the medical system in which the patient resides influence the composition of the team.^{30,31} Physiatrists, or rehabilitation medicine physicians, are educated in medicine and rehabilitation to treat patients and refer to, and/or supervise, other skilled rehabilitation professionals.²⁹ These physicians typically are responsible for the care of arthritis patients. However, in some circumstances, the rheumatologist may be the only physician involved in the patient's care. Other rehabilitation professionals involved in the care of these patients are primary care physicians, nurse practitioners, nurses, physical therapists, occupational therapists, social workers, nutritionists, psychologists, podiatrists, and vocational rehabilitators, who work with the patient's family.

Comparative studies of team care delivery versus individual practitioner models indicate that coordinated team efforts yield better outcomes.³²⁻³⁴ In all cases, the patient is the focal point of the team. Traditional models of team care are categorized as interdisciplinary, multidisciplinary, or transdisciplinary. In the interdisciplinary model, each professional conducts an independent patient evaluation and shares this information during team meetings to facilitate the development of integrated team goals. Negotiation and collaboration are prevalent principles. Multidisciplinary team care does not foster intercommunication between professionals in a coordinated manner.³⁵ Rather, each professional conducts an examination and develops his/her goals for care in concert with the patient, and separately documents findings. The transdisciplinary model allows for the transference of professional roles. This model crosses professional boundaries (e.g., a physical therapist can do some functions of a nurse).³⁶⁻³⁸ Any of these models of care may occur in an inpatient or outpatient setting.

Although team care has been widely used in Europe, this is not the case in North America, in part because of budgetary constraints and shortages of health care professionals, especially in rural areas.³⁹ Consequently, innovative care models such as the clinical nurse-specialist model,^{36,38} the primary therapist model,³⁷ and telemedicine have emerged.

INTERNATIONAL CLASSIFICATION OF FUNCTIONING, DISABILITY, AND HEALTH: A FRAMEWORK FOR REHABILITATION MANAGEMENT

The International Classification of Functioning, Disability, and Health (ICF) of the World Health Organization

provides a framework for the development and implementation of rehabilitation interventions.¹ The ICF systematically organizes various aspects of an individual's health condition. The term *functioning* is used to describe body functions, activities, and participation; the term *disability* refers to impairments, activity limitations, and participation restrictions. The ICF also considers environmental and personal factors that interact with body functions, body structures, activities, and participation.¹ This framework integrates aspects of the biopsychosocial medical model with an ecological perspective. The equal emphasis on ecological factors, such as personal and environmental contextual factors, helps rehabilitation specialists identify and address elements that may facilitate or present barriers to obtaining independence. The ICF definitions serve as a common language for providers to communicate about patients' health conditions, interventions, and performance of activities and participation in society.¹⁻⁸ (Figure 38-1). Researchers use the ICF to solidify and examine core constructs relevant to clinical studies of arthritis rehabilitation.^{3,6,7} These core sets have been compared with well-validated clinical outcome measures and help to identify the most salient outcome measures for use in rehabilitation clinical trials.^{3,39}

ASSESSMENT TOOLS AND THE REHABILITATION CYCLE

The first step in rehabilitation is problem identification based on a comprehensive history and physical examination using reliable and valid health measurements. Results from such measurements are used in turn to develop the intervention and to evaluate outcomes. Rehabilitation health professionals use a wide variety of assessments, including the following:

- Technical measures: electrophysiologic, biomechanical, and computerized devices
- Clinical tests: ligament laxity tests, range-of-motion and strength testing
- Performance measures: gait velocity, mobility tests
- Patient-centered measures: patient and proxy self-reports on health status, quality of life, and health preferences

Because the primary goal in rehabilitation is to restore function and enable a return to normal life, the emphasis of a rehabilitation examination is on assessment of functioning and societal participation.³⁵

Body structures and function elements such as joint motion may be assessed subjectively through simple observation, goniometry, or high-speed cinematography. Goniometry is most commonly used in the clinical setting because it is inexpensive, is easy to perform, and is psychometrically sound. Muscle strength is frequently assessed using manual muscle testing procedures, although its reliability and validity varies by joint location and by disease. Quantitative methods of maximal isometric strength measurement with hand-held dynamometers are reliable in patients with inflammatory arthritis^{35,40,41} and in those with degenerative lumbar spinal stenosis.⁴² Hand-grip strength can be measured reliably with a hydraulic hand dynamometer.⁴³

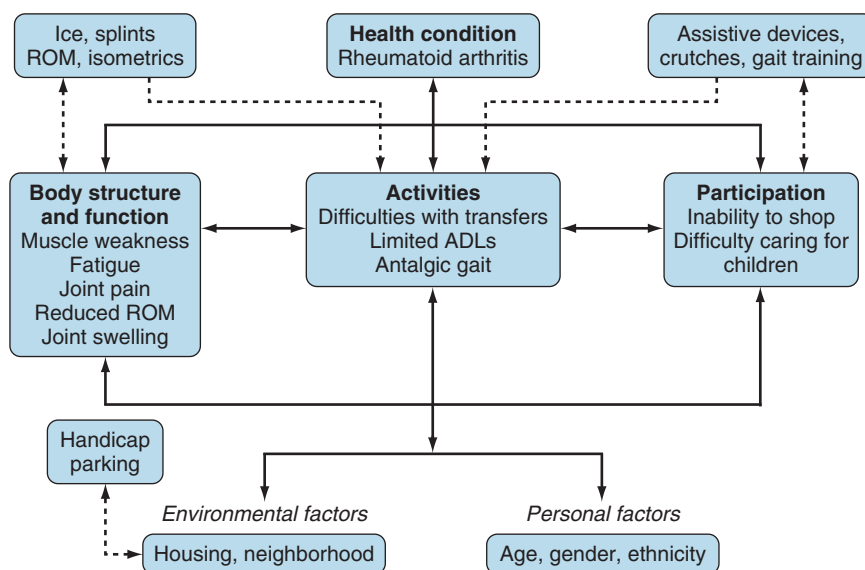

Figure 38-1 Application of the International Classification of Functioning, Disability, and Health (ICF) in inflammatory arthritis and corresponding rehabilitation interventions. Dotted lines represent modalities and physical therapy interventions or public health interventions, which target various aspects of the ICF model. ADLs, activities of daily living; ROM, range of motion.

Gait velocity, calculated as the time needed to walk a specific distance, is commonly measured to assess walking mobility⁴⁴ and serves as a test of lower extremity function. The “Timed Up and Go” test⁴⁵ is a basic mobility test that measures the time it takes a patient to rise from an arm chair (seat height of 46 cm and arm height of 65 cm), walk 3 meters, and return to and sit down in the chair. This performance measure has been tested in a variety of patients and has been used to establish normative values for different age groups.

Patient self-report measures developed and tested over the past two to three decades are widely implemented in the core-set measures for various rheumatic conditions. In inflammatory arthritis, the Health Assessment Questionnaire (HAQ) assesses dimensions of health, including disability, pain, medication effects, and costs of care.⁴⁶ A modified version of the HAQ, known as the MHAQ, uses fewer items and maintains good psychometric properties, although differences in scores for disability are evident between the HAQ and the MHAQ.⁴⁷ A disease-specific version of the HAQ is available for persons with rheumatoid arthritis (RA-HAQ). The Katz Index of activities of daily living and the MacMaster Toronto Arthritis Preference Disability Questionnaire (MACTAR) also measure general activities of daily living. The MACTAR is unique in that it allows patients to choose which activities are important to them.³⁵

A range of patient-oriented, disease-specific measures of function and symptoms may be used to assess pain, psychological status, well-being, fatigue, sleep, and quality of life.¹² Thus it may be difficult for clinicians and researchers to select the most appropriate measure for their purpose. To address this problem, one can refer to the ICF framework of functioning, which provides a clear picture of which health domains are addressed by each of the measures. Linking rules have been established to relate technical and clinical measures, health status measures, and interventions to the ICF.⁴

WHAT DO CURRENT GUIDELINES FOR REHABILITATION MANAGEMENT OF SELECT ARTHRITIDES SUGGEST?

Clinical guidelines for arthritis management consistently promote the use of exercise, physical activity, and physical therapy.⁴⁸⁻⁵⁹ Recommendations are based on substantial evidence from randomized controlled trials of exercise in arthritis⁶⁰⁻⁶⁵ indicating moderate effect sizes for the benefits of exercise for pain relief, function, and muscle strength. However, specific exercise prescriptions are not provided. Lack of details regarding exercise prescription originates from inconsistency in information regarding the intensity, frequency, mode, and duration of exercise in early clinical trials of exercise.⁶⁵ More recent studies adhere to standardized reporting criteria such as the GRADE (Grading of Recommendations Assessment, Development, and Evaluation) framework,⁶⁶ thus providing detailed information about exercise interventions to enable better synthesis of data. Information regarding accepted clinical rehabilitation is provided in the section addressing specific diagnoses and interventions.

NONPHARMACOLOGIC INTERVENTIONS TO MANAGE ARTHRITIS

Nonpharmacologic interventions used to manage arthritis symptoms include rest (total body or local), massage and trigger point techniques, exercise, assistive devices, orthotics and splints, counseling, education and self-management, manual therapy/mobilization, gait training and instruction in ambulatory devices, mobility devices, ergonomic modifications, and vocational rehabilitation. Table 38-1⁶⁷⁻⁷⁶ provides a description of each of these interventions and their role in the management of arthritis. Among these, exercise, patient education programs, and self-management interventions are the best studied and the most effective. Across

Table 38-1 Definitions, Descriptions, and Purposes of Common Rehabilitation: Interventions to Manage Symptoms of Arthritis

Intervention	Description
Energy conservation/total body rest	Important with inflammatory rheumatic diseases to have intermittent rests during the day (half hour) and 8-10 hours of rest per night. ⁸⁷
Local rest/resting splints	Resting splints (worn at night or during periods of total body rest to prevent joint movement) provide local rest to joints and maintain joint alignment. In RA and other systemic inflammatory disorders, resting wrist splints are well tolerated and effective. ¹⁴
Manual therapy/joint mobilization/manipulation	Performed as low- or high-velocity, small- or large-amplitude passive movement techniques. Flexibility and strengthening exercises follow manual therapy/mobilization to gain full benefit. Evidence is strongest in treating hip and low back disorders, but effects are small. ⁶⁷
Trigger point therapy	Used for muscle pain. Consists of ischemic compression of trigger points, followed by isotonic contractions or muscle tissue stretching. Additional techniques include myofascial release, trigger point injections, trigger point dry needling, and intramuscular manual therapy. A local twitch response, provocation of referred pain, and subsequent relaxation of the taut band indicate successful application. ³⁵
Massage	Increases local blood and lymph flow, facilitates muscle relaxation, and reduces muscle stiffness, pain, and spasm. Techniques include gliding, kneading, deep friction, and percussion. Gliding and kneading reduce muscle tension, improve circulation, and decrease edema. Friction breaks up adhesions. Lymph drainage increases lymph flow and decreases edema. ⁶⁸ Massage is contraindicated over malignant tumors, open wounds, thrombophlebitis, and infected tissues. Lymph drainage should be avoided in patients with congestive heart failure. ^{35,69}
Exercise	
Range-of-motion (ROM) and flexibility exercises	Maintain joint movement and function and may be performed passively (by therapist) or may require active patient participation. In active-assisted exercises, the patient exerts some force with joint movement but is assisted by the therapist. Active ROM exercises require the patient to exert muscle effort to achieve the desired ROM. ^{35,87} Flexibility or stretching exercises enhance extensibility of muscle tissue. Stretching is best performed using gentle, smooth movement, and then holding the stretch for 2-15 seconds.
Isometric (static) exercise	Muscle contraction performed without a change in joint range or muscle length. These exercises produce less strain on joints than is produced by dynamic exercise. ⁸⁷
Isotonic/dynamic/isokinetic exercise	Isotonic exercises require changes in muscle fiber length by elongating (eccentric) or shortening (concentric). These exercises involve movement through a fixed ROM at a fixed rate (velocity) against variable resistance. A machine provides resistance and rate of movement that matches exactly the force generated by the patient at any point in the range. This equipment can calculate the torque developed during the exercise activity. ^{35,82} Note: AVOID in the presence of inflammation, popliteal cysts, and joint derangement. ⁸⁷
Aerobic conditioning or endurance exercise	Provides cardiovascular pulmonary benefits, improves muscle strength, and reduces inflammation and weight. Modest effect sizes for these outcomes are achieved when exercises are performed at moderate levels of intensity for extended periods. Modes of aerobic exercise include walking, running, hiking, cycling, swimming, and stair climbing. ^{23-25,79}
Aquatic exercise, spa therapy, balneotherapy	Based on physical properties of water (i.e., buoyancy, molecule adhesion, temperature), provide physiologic benefits such as muscle relaxation and ease of movement. Exercises performed in water allow buoyancy to support body weight and unload joints. Water adhesion properties may provide resistance when exercising. Diuresis and hemodilution are physiologic effects experienced with aquatic exercise. The recommended water temperature is 33° C–34° C (92° F–94° F). A systematic review of randomized controlled trials investigating balneotherapy has reported positive findings. However, the evidence was insufficient to allow formal conclusions about the efficacy of balneotherapy for patients with arthritis. ¹⁰
Physical Modalities	
Superficial heat/cold therapy	Radiation (infrared light) and conduction (hot packs, paraffin, or water) are mechanisms for superficial heat/cold generation that are applied for 20 minutes. Superficial heat increases the pain threshold, decreases muscle spasms, and produces analgesia by acting on free nerve endings. Note: AVOID heat therapy in the presence of acute inflammation or in persons with altered sensation. Cold therapy may be applied using ice packs, ice massage, vapocoolant sprays, or cold water baths. Cold therapy induces superficial and intra-articular tissue vasoconstriction, reduces local metabolism, and slows nerve conduction, thereby reducing pain and inflammation. Complications of cryotherapy include frostbite, cold-induced urticaria, and nerve damage. Use cryotherapy with caution in patients with Raynaud's phenomenon or with cryoglobulinemia. ³⁵ Although evidence for physiologic benefits of heat and cold therapy indicates small effects, ⁹ patients report psychological benefits.
Electrotherapy	Uses electricity to stimulate nerves and muscles and to alleviate pain. Surface electrodes are the common transfer medium. Only electro-acupuncture and dorsal horn stimulation use needle electrodes percutaneously. Electrotherapy uses direct continuous galvanic currents and modulated direct currents. Galvanic currents decrease pain conduction in slow unmyelinated nerve fibers (C fibers) to reduce pain. Modulated middle-frequency electrotherapy results in inhibition of pain-related potentials at spinal and supraspinal levels. Electrical stimulation of fast-conducting myelinated nerve fibers can partially decrease pain through inhibition of pain impulses carried more slowly by unmyelinated fibers. Faster impulses arrive at the level of the dorsal horn first and "close the gate." Transcutaneous electrical nerve stimulation (TENS) is used for musculoskeletal pain, posttraumatic or postsurgical pain, peripheral nerve injury, neuropathic pain, and sympathetically mediated pain. ³⁵ Electrotherapy is contraindicated in patients with cardiac pacemakers or implanted cardiac defibrillators, and is used with caution in patients with atrophic skin. ³⁵ A systematic review of randomized controlled trials of TENS in arthritis reports inconsistent results in managing RA symptoms ¹³ and low back pain, and some benefits for pain and knee stiffness in patients with knee osteoarthritis. ⁷⁰

Continued

Table 38-1 Definitions, Descriptions, and Purposes of Common Rehabilitation: Interventions to Manage Symptoms of Arthritis—cont'd

Intervention	Description
Deep tissue heating/ultrasound and diathermy	Parameters for application vary by the device; the device must be applied by a skilled provider owing to the risk of deep tissue burns of the skin, fat, muscles, and bones. Heating occurs mostly at tissue interfaces (e.g., bone–soft tissue interfaces). Ultrasound may penetrate 7–8 cm of fat, but less than 1 mm of bone, depending on the energy level and frequency chosen. In practice, ultrasound with frequencies of 0.1–1 MHz can increase temperature by 4° C–5° C at depths of 7–8 cm. ³⁵ Two systematic reviews of ultrasound ^{8,71} reported small benefits for pain, knee and hand stiffness, grip strength, and tender and swollen hand joints. ⁸ <i>Note:</i> Avoid deep heating in patients with altered sensation, implants, or history of cancer. Ultrasound must be applied using continuous movement over joints and bony surfaces or in a water bath to avoid heating of bone.
Devices to Stabilize and Protect Joints	
Orthotics/braces	Orthotic devices include braces, splints, corsets, collars, and shoe modifications. Orthotic devices restore or maximize function by altering biomechanics through stabilizing, realigning, and/or maximizing joint position, thereby reducing pain. Orthotics provide some pain relief but inconclusive evidence of improved function long term. ^{18,19} Successful prescription and use of orthotics require the identification of functional limitations (on all ICF levels) and patient collaboration to adjust the orthotic. Devices can be simple and inexpensive, but may be specially designed and consequently expensive. ³⁵ Bracing is prescribed to stabilize joints. The most common are knee braces typically prescribed for OA. ¹⁹
Dynamic splints	Dynamic splints maintain joint alignment and reduce pain during functional activities. The most common dynamic splints used in RA are functional wrist splints, although many others are available for the small hand joints. In OA, thumb splints are common. A Cochrane review from 2003 concluded that dynamic wrist splints significantly increase grip strength but do not impact pain, morning stiffness, pinch grip, or quality of life. No evidence suggests that resting splints changed pain, grip strength, or the number of painful or swollen joints. Patients preferred using these splints to nonuse. ^{20,35}
Collars/corsets	Cervical collars include soft collars, Philadelphia collar, and sterno-occipitomandibular plaster immobilization. These provide varying levels of stability. None prevent subluxation or displacement. ⁷² Patients with night pain resulting from a cervical disk syndrome may profit from wearing a soft collar at night. Corsets and abdominal binders provide feedback but limited stability to patients in terms of body position. ³⁵
Assistive devices	A multitude of devices may be used to assist function and reduce barriers to independence. Examples include button hooks, long-handled reachers, sock aids, modified eating utensils (padded handles), bottle openers, and modified container lids. A physical or occupational therapist may recommend modified door handles, a raised toilet seat, a commode, safety bars on the bathroom wall, or a lift in the bath to ensure safety and maximize independence with hygiene activities.
Mobility devices	Mobility devices, such as canes, crutches (axillary, forearm, and platform), wheeled walkers, and wheelchairs, are used when walking is limited by lower extremity joint instability, pain, weakness, and fatigue or balance problems. These devices are easily accessible and provide immediate assistance, but they require more physical effort than is required for normal ambulation. The choice of a mobility device is based on impairments and resulting disability (e.g., patients with RA with bilateral upper extremity involvement and leg weakness may be safer ambulating with platform than axillary crutches). Patients with balance disturbances and leg weakness may be better suited for walkers. The device type also impacts the weight-bearing status. For example, a single-point cane can bear about 25% of body weight, axillary or forearm crutches about 50%, and a wheeled walker more than 50%. ⁷³ Wheelchairs are necessary if patients are unable to walk with devices. In these cases, a wheelchair can improve the quality of life by maintaining some mobility. Persons unable to navigate a manual wheelchair can profit from an electrical chair. Accidents can occur while traversing ramps, sidewalks, and streets. ³⁵
Vocational rehabilitation	Vocational rehabilitation is an interdisciplinary approach that enables patients to acquire and maintain gainful employment and varies among countries. A common feature consists of problem assessment at work and the development of individual solutions. Studies demonstrate that vocational support prevents or delays work disability and improves fatigue and mental health. ⁷⁴
Work hardening/functional restoration programs	These highly structured, goal-oriented, individually tailored programs are provided by an interdisciplinary professional team to address functional, physical, behavioral, and vocational needs to facilitate return to work. ⁷⁵ Work hardening programs bridge the gap between initial injury and return to work. Most programs include a formal worksite ergonomic to address workplace design issues and to reduce injury risk while improving function, as well as social interventions. The Commission on Accreditation of Rehabilitation Facilities defined and developed standards for work hardening practice to standardize program content and implementation. ⁷⁵ Work hardening programs integrate real or simulated work activities to model appropriate behaviors and assess functional, biomechanical, neuromuscular, cardiovascular/metabolic, behavioral, attitudinal, and vocational performance. ⁷⁵ A systematic review of these programs provides evidence for significant reductions in sick days. ¹²
Self-management and patient education	Patient education is defined as a set of planned educational activities used to improve a patient's health behaviors and/or health status. Most patient education programs are provider driven and developed. Self-management programs are patient oriented and patient active, and combine education with cognitive-behavioral strategies to influence patients' attitudes toward disease and disease management. ⁸⁵
Cognitive-behavioral therapy (CBT)	CBT acknowledges that pain and its resulting disability are influenced by somatic pathology, and by psychological and social factors. In general, three behavioral treatment approaches are distinguished: operant, cognitive, and respondent. The primary focus is to reduce disability. A review of 21 studies found no significant differences between the various types of CBTs; also, CBTs did not differ from exercise. A conclusion regarding whether clinicians should refer patients with chronic low back pain to behavioral treatment programs or to active conservative treatment was not possible. ⁷⁶

diseases, exercise interventions, whether dynamic or static, yield moderate improvements (effect sizes of 4 to 6) in strength, pain, and function, and produce small to moderate improvements in mood, quality of sleep, sleep patterns, and psychological well-being.^{16,17,63-65,77-81} Exercise also reduces inflammation.⁸²⁻⁸⁴

Patient education is an integral component of rehabilitation management. Patient education programs provide structured information about disease, medications and their use, when and how to perform exercise, disease management strategies (e.g., energy conservation, rest), and community resources. These programs are distinct from self-management interventions in that they are often provider driven and formulated, and focus on information dissemination versus behavioral interventions. For example, ankylosing spondylitis education programs educate patients about their disease, medication use and side effects, importance of good posture, extension exercises, activities in life that promote extension (playing on the floor with toddlers), and coping skills.

Self-management programs are patient focused, patient driven, and action oriented.⁸⁵ These programs combine education, behavioral interventions, and cognitive strategies to enable patients to problem-solve, cope, and develop strategies to maximize function and independence. A focus of these programs is to assess and influence patients' attitudes and beliefs about disease and their ability to manage their disease. Self-management programs demonstrate benefits with respect to disease outcomes^{85,86} and have proved cost-effective.⁸⁶

Evidence of the benefits of physical modalities, therapeutic relaxation techniques (massage, trigger point therapy) and splinting, orthotics, and gait deviation interventions varies across intervention type and disease. Overall, the evidence is weak.^{8-10,13,87} However, it is important to note that relaxation and physical modalities are adjunct therapies designed to prepare a patient for dynamic exercise, flexibility training, or gait training and are not stand-alone interventions.⁸⁷ Additionally, many patients report satisfaction with and preference for these therapies.⁸⁸

PRINCIPLES GUIDING REHABILITATION IN PEOPLE WITH ARTHRITIS

Research and clinical management outcomes suggest the need for the following guiding principles for rehabilitation in the care of persons with arthritis:

- Primary, secondary, and tertiary programs are an integral aspect of the care of persons with arthritis. Primary prevention focuses on preventing disease. Secondary prevention refers to detection of disease before it becomes symptomatic. Tertiary prevention, the most common in arthritis, focuses on interventions for persons already experiencing disease symptoms to ameliorate symptoms and to maximize function and independence.
- Exercise prescriptions for persons with systemic inflammatory diseases are developed on the basis of the disease state (active vs. inactive disease), disease severity, patient preferences and goals, medications used and their corresponding side effects, and latency periods.⁸⁷

- Persons with arthritis are less aerobically fit than their healthy counterparts.^{21,24,89}
- Asymptomatic heart disease may be disproportionately present in persons with systemic lupus erythematosus, rheumatoid arthritis, and other inflammatory conditions; therefore, heart rate and blood pressure monitoring is needed before exercise sessions and at periodic intervals during exercise and cool-down.⁸⁷
- Exercise response in persons with systemic inflammatory disease is altered, and careful monitoring of cardiovascular pulmonary response is needed during exercise testing and participation.
- Dynamic resistance strengthening exercises should be avoided in the presence of joint derangement and popliteal cysts.⁸⁷
- During periods of active myositis and elevated creatine phosphokinase (CPK) levels, activities should be limited to range-of-motion exercise and functional activities of daily living, and rest should be encouraged.

The Centers for Disease Control and Prevention (CDC) in conjunction with the American College of Sports Medicine (ACSM) has established guidelines for physical activity to promote the health of all Americans, including persons with arthritis²⁸ (Table 38-2⁹⁰). The CDC deliberately framed these recommendations as minutes of exercise versus traditional physiologic parameters to enable consumers to better interpret activity expectations and attempt to meet these recommendations. Presently, physical inactivity among persons with doctor-diagnosed arthritis in the United States is a major public health issue; only 17.2% of people meet the CDC recommendations for moderate physical activity.⁹¹

REHABILITATION OF SELECT ARTHRITIDES

In this section, select rheumatic conditions are discussed, along with evidence for rehabilitation interventions. Given the variety of rheumatic diseases, conditions that have similar attributes are grouped together, although they are distinct entities. In this manner, the rationale for interventions based on similar impairments, functional limitations, and activity participation can be delineated. Although not all diseases will be discussed, this section provides the intervention algorithms used in management of these conditions.

Table 38-2 Centers for Disease Control and Prevention and American College of Sports Medicine Guidelines for Physical Activity

30 minutes of moderate physical activity 5 days a week or 20 minutes of vigorous activity three times per week
<i>Moderate activity</i> is defined as an increase in breathing or heart rate; perceived exertion in the range of 11-14 out of 20 on a perceived exertion scale ⁹⁰ or 3-6 metabolic equivalents of task; or any activity that burns 3.5-7 calories per minute (kcal/min). ²⁸

Common Impairments and Rehabilitation Interventions in Rheumatoid Arthritis and Inflammatory Arthritis

Both rheumatoid arthritis (RA) and psoriatic arthritis (PsA) are chronic systemic inflammatory rheumatologic disorders affecting connective tissues and joints. Of the two conditions, RA is more prevalent. Although the origin and prevalence of RA and PsA differ, similarities have been noted with respect to symptoms. For example, patients present with polyarticular symmetric joint involvement, malaise, morning stiffness, pain that is relieved with activity, muscle weakness, enthesitis and/or plantar fasciitis, and cardiovascular pulmonary involvement. Both diseases are characterized by exacerbations and remissions. Differences between these diseases are noted with respect to the joints involved, integumentary involvement, dactylitis,⁹² and predominant pathology. The primary pathology in PsA is enthesitis, and the axial skeleton may be predominantly involved. Chronic inflammation eventually may lead to spinal ankylosis, significantly impacting trunk range of motion and rib cage excursion. RA is a disease of the synovium that typically involves the hands, feet, wrists, and weight-bearing joints. Although RA does not affect most of the spine, subluxation of the atlantodental joint can occur.⁸⁷

Systemic features of these conditions lead to impairments such as fatigue, malaise, fever, sarcopenia, reduced aerobic capacity, restricted joint range of motion, postural instability, cardiovascular pulmonary dysfunction, and depression.^{93,94} Both conditions are associated with significant disability and early death. Medical management of these conditions includes the use of biologics, disease-modifying antirheumatic drugs (DMARDs), steroids, and nonsteroidal anti-inflammatory agents. Although responsiveness to DMARDs varies by disease, data suggest that patients with RA are more responsive to methotrexate, whereas those with PsA are more responsive to leflunomide.⁹³ Rehabilitation professionals must be aware of indications of the need for these medications, potential side effects, and the latency period to effectiveness if they are to develop treatment plans that adjust as responsiveness to medications increases.

Given the fluctuating nature of both diseases, the selection of rehabilitation interventions varies on the basis of disease activity. Figure 38-2 provides an intervention algorithm that illustrates the different modes of exercise and rehabilitation interventions used to manage these conditions during acute, subacute, and chronic stages of disease. When RA or PsA is highly active, patients may report low-grade fever, fatigue, or malaise, and may present with warm, swollen, and tender joints. Adaptive shortening of soft tissues, joints, and tendons may occur secondary to inflammation and as the result of protective splinting of joints in response to pain. In RA, subluxation of the metacarpophalangeal and interphalangeal joints, as well as ulnar deviation of the fingers and radial deviation of the wrists, is prevalent, whereas with PsA, dactylitis may be present.⁹² With both conditions, soft tissue inflammation may lead to atrophy of the foot intrinsic muscles and loss or subluxation of plantar fat pads. Because of this, patients may present with plantar fasciitis and enthesitis. Myositis may also be present. Eventually, loss of cartilage may result, with severe

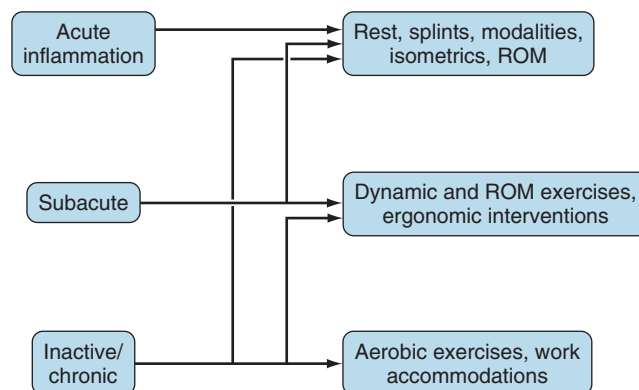

Figure 38-2 Rehabilitation intervention algorithm to manage inflammatory arthritis. ROM, range of motion.

disease and joint subluxation and derangement. These joint changes may lead to functional limitations, gait abnormalities, and deconditioning.^{87,92}

Interventions used to manage acute inflammatory symptoms include patient self-management strategies, gentle range-of-motion exercises, isometric (static) exercises, physical modalities, total body rest, and splints. The frequency and intensity of exercises are generally set at three to five repetitions, twice a day. To enhance adherence, patients are instructed to conduct daily joint checks, that is, a simple check of each joint to determine which are most limited and can serve as the focus of exercises for that day. Self-management interventions focus on energy conservation strategies. Patients are advised to sleep 8 to 10 hours per night and to take frequent rests during the day. Resting and dynamic splints are provided to maintain joint alignment, reduce pain, and control inflammation. Although resting splints are used when sleeping and serve to hold the joints in a neutral position, restricting all movement, dynamic splints are designed to allow joint movement and accommodate functional activities. During the acute inflammatory stage, cold therapy (cold packs, ice massage) is preferred over heat to reduce swelling and alleviate pain. However, thermal modalities (heat/cold) are contraindicated in persons with altered sensation and vascular conditions.⁸⁷ It is important to evaluate the need for assistive/adaptive devices (e.g., long-handled reachers) and ambulatory devices to maximize function and independence. Ambulatory devices and orthotics are particularly important in the presence of foot involvement and deformities in that they redistribute weight and alter lower extremity biomechanics. Orthotics are also shown to improve function and reduce pain.¹⁸ When wrists and hands are involved, platform attachments to assistive devices are warranted. In all cases, patient preferences need to be elicited and considered when ambulatory devices are selected, to ensure adherence.

When symptoms subside (i.e., subacute stage), more aggressive interventions can be incorporated. The program may be modified to include increased repetition of range-of-motion exercises with progression from isometric to dynamic exercises (five to ten repetitions of each exercise, three times per day). However, if myositis or popliteal cysts are present, active resistive exercise should be avoided.

Flexibility exercises are initiated to reduce soft tissue tightness and contractures. Before stretching, heat therapy and massage may be used to reduce muscle spasm and enhance joint mobility. Clinical trials of thermotherapy report small effects for relief of muscle spasm, pain, and extensibility of soft tissue.⁹ Transcutaneous electrical nerve stimulation (TENS), laser, massage, and trigger point therapy provide inconsistent results but small benefits.^{8,9,13,95-98} Randomized controlled trials of exercise at moderate intensity have been conducted and have demonstrated moderate effects in improving strength, function, and mood state, and in reducing pain, stiffness, and inflammation, without deleterious effects on joints.^{12,14,15,21,82,99} Aquatic exercises are encouraged at this time to promote flexibility, improve gait patterns, maximize strength, and increase independence. The buoyancy of the water facilitates movement and reduces joint loading.

With chronic or stable disease activity, patients should transition from gentle range-of-motion exercises to dynamic strengthening exercises with resistance (eight to ten repetitions a day). Studies suggest that dynamic exercises can effectively increase muscle strength, physical capacity, and aerobic capacity without causing deleterious effects.²¹ It is imperative to initiate aerobic exercises (30 minutes, three to five times per week) to address cardiovascular risk, improve aerobic performance, and increase muscle strength.^{100,101} Patient counseling regarding general physical activity and active lifestyles should be emphasized to prevent secondary effects of inactivity.^{27,28,102,103} The most common modes of physical activity and exercise include low-impact exercise such as walking programs, aquatics, dance, and cycling, and dynamic exercises with resistance. Recent clinical trials of high-impact physical activities report significant improvements in aerobic capacity, grip strength, physical activity, anxiety, and depression. Benefits were maintained after 1 year.²⁶ These exercises appear to be safe and effective, except in the presence of joint changes in large weight-bearing joints, joint derangement, and cartilage loss before initiation of weight-bearing activities.

Common Impairments and Rehabilitation Interventions in Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a systemic inflammatory disease that predominantly affects women in their childbearing years and is more common among African-Americans. Its cause is unknown. Systemic lupus erythematosus affects multiple organ systems, including the joints, skin, kidneys, heart, lungs, brain, and gastrointestinal tract. Fatigue is prevalent and may arise from myositis, anemia, depression, pulmonary disease, or deconditioning. Unlike in RA and PsA, joint involvement is uncommon, although if present, the small joints of the hands, especially the proximal interphalangeal joints, are most commonly involved, and recommendations similar to those for RA apply. Aseptic necrosis of the hip may occur and may require total joint arthroplasty.⁸⁷ Instruction in the use of assistive devices (crutches, canes) may help to unload painful hip joints. With unilateral hip disease, use of the device on the contralateral side reduces acetabular loading and hip abductor muscle activity, thereby reducing joint hip load and pain.

Asymptomatic coronary heart disease is a major cause of mortality. The physical examination should include a comprehensive cardiovascular pulmonary system review, and interventions should focus on exercise modes to enhance cardiovascular performance, such as biking, walking, and dynamic exercises at moderate intensity (50% to 70% one repetition maximum). For safety, vital signs are assessed at baseline and at regular intervals during the exercise session.¹⁰⁴ Patients who are severely deconditioned may benefit from interval training (short bouts of 10 to 15 minutes of exercise twice a day) to enhance aerobic conditioning. Self-management interventions are recommended to promote medication adherence and consistency in performing physical activities and exercise.

Studies of exercise in SLE are limited. In an earlier trial of endurance training using stationary cycles with individually tailored resistance settings based on submaximal exercise testing, patients with SLE demonstrated small to modest effects on function but no significant impact on VO_2max (maximal oxygen consumption).¹⁰⁵ A recent review of exercise for patients with SLE concluded that patients with mild to moderate SLE benefit from exercise of moderate to high intensity, and significant benefits can be demonstrated for aerobic capacity, fatigue, physical function, and depression.¹⁰⁶

Common Impairments and Rehabilitation Interventions in Osteoarthritis

Osteoarthritis (OA) is a progressive, multifaceted disease of the cartilage that can lead to cartilage and bone loss. Typical joints involved include hips, knees, spine, and hands (distal and proximal interphalangeal joints, first carpometacarpal, and first metatarsal phalangeal). Intrinsic and extrinsic factors, such as joint injury, malalignment, trauma, obesity, and quadriceps weakness, are associated with the development of OA. Patients typically note short-term morning stiffness (<30 minutes) or stiffness after prolonged sitting or inactivity. The combination of excess weight and poor joint biomechanics increases the risk of OA about threefold.

Patients typically report specific joint pain, muscle weakness, and restrictions in range of motion. Osteophytes and bone fragments may produce radicular pain if a nerve root is compressed and can limit movement. Herberden's nodes at the medial and dorsolateral aspects of the distal interphalangeal joints and/or Bouchard's nodes at the proximal interphalangeal joints may be present. Hip pain is frequently located at the joint line but may radiate to the groin, buttocks, anterior thigh, or knee. Reduced hip range of motion impacts function and hygiene. Knee osteoarthritis may present as knee instability, restrictions in joint range of motion, crepitus, pain with loading activities, or buckling of the leg with transfers and ambulation.

Common interventions to manage OA include dynamic strengthening exercises (both open and closed chain exercises), core stability exercises, education, balance activities, aerobic exercises (biking, swimming), joint mobilization and manipulation, bracing (severe cases), gait training, use of orthotics, and appropriate footwear.⁵⁹ Thermotherapy including deep heat applications (ultrasound) may help to

alleviate pain, enhance tissue extensibility, and reduce stiffness.¹⁴ Paraffin is useful for hand treatment because it provides a medium for dispersing heat over small joints. Exercise therapy can effectively improve function, reduce stiffness, and maximize independence. Recent reviews and synthesis of the literature on exercise for knee OA and hip OA, provided at varying intensities, frequencies, and durations, report significant moderate gains in muscle strength function (effect sizes ranging from 0.3 to 0.6).^{*} The emphasis of patient education is on joint protection techniques, activity modification, weight reduction, and strategies to unload the joint.

Manual therapy techniques for patients with knee OA include tibiofemoral and patellofemoral joint mobilization. Manual therapy interventions are followed by stretching of the quadriceps, hamstrings, tensor fascia, iliotibial band (ITB), hip flexors, and gastrocnemius soleus, and soft tissue mobilization techniques. These combined interventions yield benefits for joint range and function.^{65,78} Open-chain isometric exercises such as quadriceps exercises are used with progression to closed-chain weight-bearing exercises such as mini squats and step-ups.¹⁰⁹ Balance activities such as exercises performed on balance boards, single-leg stance, and hop are designed to facilitate co-contraction, and coordination of muscle firing is a useful exercise technique for promoting knee stability. Sensorimotor interventions may provide necessary proprioceptive input, but their efficacy is still unknown.¹¹⁰ Lateral wedge orthoses in patients with medial compartment knee OA assist with altering biomechanical loading at the knee and are well tolerated.¹⁹ With progressive disease and instability, knee braces are used to decrease medial compartment pressures resulting from varus positioning. Systematic reviews of the effects of knee bracing report limited benefits for pain relief and function. However, it is important to note that adherence to these devices is problematic.¹⁹

Hip OA often results in restrictions in internal hip rotation and impacts gait. Manual techniques for the hip joint aim to improve the elasticity of the joint capsule and surrounding muscles. The combination of mobilization and exercise appears to be more effective than exercise alone.^{16,66} Ambulatory aids (canes, crutches, walkers) are used to unload the joint and allow patients to maximize independence.

Common Impairments and Rehabilitation Interventions in Ankylosing Spondylitis

Ankylosing spondylitis (AS) is a systemic inflammatory disease that targets the sacroiliac and axial joints. Systemic features include fatigue, malaise, and sarcopenia, which results in reduced engagement in physical activity. Enthesiopathy is common and impacts gait and transfers. With persistent inflammation, ankyloses of the spine can occur,¹¹¹ limiting trunk range of motion and rib cage excursion. AS may also involve the hip and shoulder joints. Cardiovascular pulmonary manifestations may be seen; when they are

coupled with trunk and rib cage restrictions, as well as the potential for costochondritis, aerobic capacity may be dramatically impacted.⁸⁷

Rehabilitation interventions for patients with AS include physical modalities such as thermal therapy to relax soft tissues and prepare the patient for flexibility exercises, manual therapy, assistive and ambulatory devices, orthoses, and functional activities. The principles of physical modalities for persons with AS are similar to those for those with PsA. Flexibility exercises are used to promote extension and help maintain a neutral spine. Incorporating posture and flexibility exercises into daily routines can enhance adherence and maintain joint range. For example, patients can be encouraged to read the newspaper while lying prone on the floor or to take stretch breaks during the day to avoid long periods of time sitting in front of a computer. Given the potential for reduced rib cage excursion, deep breathing exercises are used, although their efficacy is unproven. Dynamic progressive strengthening exercises of the postural muscles (at moderate intensity) and motor control activities are useful for maximizing strength and function. A Cochrane review of three randomized controlled trials reported greater improvements in spinal mobility and patient global assessment among patients participating in supervised group exercise.¹¹² Aquatic exercises provide a nice alternative, and the buoyancy of the water can facilitate movement. However, studies of aquatic therapy for persons with AS are limited and, at best, show small effects.¹¹³ Ambulatory and assistive devices may be warranted as the disease progresses or to unload a painful hip. Patient education typically focuses on smoking counseling (cessation or prevention), joint protection, energy conservation, instruction in exercise, and coping strategies.

Strategies to Increase Adherence to Exercise and Rehabilitation

Rehabilitation interventions require active participation of the patient and a commitment to adhere to the regimen for benefits to be acquired. The team must always maintain a patient-centered focus and must engage the patient in mutual goal setting and problem solving. Clear, concise communication about treatment expectations and the establishment of small, progressive, and achievable milestones are important. Potential barriers to exercise such as fear of joint damage or exacerbation of pain, lack of social support for exercise, fatigue, lack of transportation to a pool, or cost make it imperative to develop an appropriate and acceptable intervention plan. With systemic inflammatory diseases, disease activity primarily influences the mode, frequency, and intensity of exercises prescribed, although other factors influencing intervention selection include disease severity, systemic manifestations and other comorbidities, and patient preferences. Self-management programs are a vehicle to promote adherence to exercise and active lifestyles and have been found to be highly effective.⁸⁵ Linking patients to community resources such as Arthritis Foundation exercise programs (Walk with Ease, Fit and Strong!) allows patients to develop social networks to share their experiences in living with arthritis and provides a venue for exercise.

*References 16, 61-65, 77, 78, 87, 107, 108.

SUMMARY AND CONCLUSIONS

Rehabilitation interventions comprise a vast array of treatments. Physical modalities are adjuncts to exercise and self-management and provide small benefits with respect to pain relief. Evidence of the benefits of orthotics and bracing is weak, although adherence is a factor that influences results. Exercise is the most intensively studied intervention; it provides modest benefits for pain relief, strength, function, mood state, and joint stiffness across most disease entities. Selection of rehabilitation interventions for systemic inflammatory diseases is influenced primarily by disease state, but is also dependent on disease severity, medication latency periods, comorbidities, disease severity, and patient preferences.

Pregnancy in the Rheumatic Diseases

ELIZA F. CHAKRAVARTY • MEGAN E. CLOWSE

KEY POINTS

The majority of women with autoimmune diseases will have healthy and uneventful pregnancies, and the risk-benefit ratios for medication use during pregnancy will improve pregnancy outcomes and reduce maternal and fetal risks.

The best outcomes result from conception occurring when the disease is in remission or clinically quiescent.

With few exceptions, clinical or laboratory parameters are unable to predict whether underlying disease activity will improve, worsen, or remain the same during pregnancy.

Potentially teratogenic medications should ideally be discontinued several months before conception.

At times women with underlying autoimmune disease require ongoing disease-modifying or immunosuppressive therapy during pregnancy to treat persistently active disease or flare-ups.

U.S. Food and Drug Administration pregnancy categories for medication safety for use during pregnancy are not routinely updated and may not accurately reflect increased experience during pregnancy.

Increased rates of premature delivery or small-for-gestational age infants may be seen in many autoimmune diseases.

The majority of autoimmune diseases display a female predominance, and, with the exception of giant cell arteritis, may present during the childbearing years. With improved treatment options for many autoimmune diseases that may prevent or retard functional disability or progressive organ damage from active disease, an increasing number of affected women will be able to face the physical challenges of childbearing and childrearing and may consider pregnancy as an important component of a fulfilling life. When considering pregnancy in women with underlying autoimmune diseases, one must take several things into account: (1) the effects of underlying disease on pregnancy outcomes; (2) effects of a pregnancy, with all of its immunologic and physiologic changes, upon an autoimmune disease; and (3) safe use of medications for effective control of autoimmune disease while avoiding adverse effects to the pregnancy or fetus.

In order for the “fetal semiallograft” to survive and grow during 9 months of exposure to the maternal immune system, the maternal immune system must undergo a complex modulation of the innate and humoral immune system, much of which is not well understood. Pregnancy had long been understood as a Th2-predominant condition,

whereby a shift of helper T cells toward a Th2 dominant state, possibly induced by increasing levels of progesterone, is necessary to establish and maintain a normal pregnancy. This theory was consistent with earlier observations that systemic lupus erythematosus (SLE, a Th2-predominant disease) may be exacerbated by pregnancy, whereas Th1-mediated autoimmune diseases (rheumatoid arthritis [RA], multiple sclerosis, and psoriasis) appear to be characterized by clinical improvement during pregnancy.¹ More recently, however, it is becoming increasingly clear that many more components of both the innate and adaptive immune systems are involved in normal pregnancy.²⁻⁵ Furthermore, many of the immunologic changes during pregnancy may be preferentially located at the maternal-fetal interface and may not be accurately sampled using peripheral blood. The trophoblast and placenta, once considered passive mediators of maternal-fetal immune trafficking, have been increasingly recognized as playing active roles in mediating inflammation, as well as in host defense.² Taken together, it is evident that understanding the immune regulation of a healthy pregnancy remains elusive, much less understanding how pregnancy-related immunologic changes interplay with an abnormal immune system stemming from preexisting autoimmunity.

Nonetheless, it is imperative to go beyond inferring that individual diseases “tend” to behave in well-defined ways during pregnancy and look at an individual woman’s risk for adverse pregnancy outcomes. Fortunately, the majority of women with autoimmune diseases who desire children will have safe and relatively uncomplicated pregnancies. However, despite significant advances in the management of pregnancy in women with autoimmune diseases, one can argue that the rates of adverse pregnancy outcomes remain unacceptably high for some conditions.

Further complicating the issue of pregnancy in women with autoimmune diseases is the continuation or discontinuation of disease-modifying agents in anticipation of or discovery of a pregnancy. Some medications are known or suspected teratogens and should be avoided during pregnancy, whereas others may be considered safer to use with less evidence of embryotoxicity. As much as it may be desirable to manage disease during pregnancy with the minimum amount of medications necessary, the risks of medication exposure during pregnancy must be balanced with the risks of untreated active inflammatory disease and its potential for adverse pregnancy outcomes.

A few general principles apply to all women with autoimmune diseases who are contemplating pregnancy or who discover an inadvertent pregnancy. First and foremost, open communication between provider and patient is critical to all aspects of contraception and pregnancy planning. In the

ideal situation, family planning discussions are conducted before a woman becomes pregnant. Open and frank discussion of the risks of pregnancy outcomes regarding underlying disease activity and medication use should be continued throughout pregnancy. It has become increasingly evident that pregnancy outcomes are optimized when conception occurs during periods of disease quiescence and when disease control can be maintained throughout pregnancy. This requires preconceptional management of autoimmune disease using medications that are safe should they be required to be continued into pregnancy to maintain disease control. Additionally, comorbid conditions including hypertension and hyperglycemia should be well controlled before conception. Consultation with specialists in maternal-fetal medicine may be helpful for comanagement of the pregnant patient with autoimmune diseases to ensure the proper monitoring for and management of disorders of pregnancy are undertaken in a timely manner. For the patient who discovers an inadvertent pregnancy during periods of active disease or with exposure to potentially teratogenic medications, counseling by both a rheumatologist and maternal-fetal medicine specialist should be offered so that the woman can make well-informed choices regarding her pregnancy. Healthy infants have been born with documented exposure to the most teratogenic medications, and patients may want to continue pregnancies despite early antenatal exposure.

SYSTEMIC LUPUS ERYTHEMATOSUS

Because SLE primarily affects women in their reproductive years and these patients have normal fertility, pregnancy is a frequently encountered dilemma. Fortunately, the majority of these pregnancies will progress without complication and result in the delivery of a healthy baby by a healthy mother. Almost half of these pregnancies, however, will encounter complications including increased lupus activity, pregnancy loss, preterm birth, and preeclampsia. The key to pregnancy success is careful planning for pregnancy, which includes timing to avoid conception during periods of disease activity and alteration of medications to avoid teratogenicity but maintain disease quiescence.

Pregnancy Outcomes

Retrospective studies of women with SLE have noted an increased rate of pregnancy loss when compared with healthy women. Among 203 women with SLE, 166 of their friends, and 177 of their relatives, pregnancy loss was twice as common (21% in SLE vs. 14% in friends and 8% in relatives, $P < .0001$) and preterm birth was three times more frequent (12% in SLE vs. 4% in friends and relatives, $P < .0001$).⁶ Prospective cohorts of SLE pregnancies report a more modest pregnancy loss rate, but these cohorts probably miss some early pregnancy losses that occur before presentation in the rheumatology clinic. What they notably show is a rate of stillbirth, typically defined as a pregnancy loss after 20 weeks gestation that is 5- to 10-fold higher than that of the general population (Figure 39-1). In a meta-analysis of 37 studies of SLE pregnancies (12 prospective and 25 retrospective), there is a higher than expected rate for miscarriage, infant death, and neonatal death (infant death at <28

Figure 39-1 The rate of pregnancy loss in prospective cohorts of pregnancies in women with systemic lupus erythematosus (SLE).^{7,11,15-18} The miscarriage rate is typically not higher than reported in the general population, though prospective registries may miss early losses that occur before rheumatology visit. The risk of stillbirth is estimated at 1% in the United States but is between 5% and 8% in most prospective SLE pregnancy cohorts.

days of life).⁷ Several studies have documented that increased SLE activity around the time of conception, hypertension, prior or current lupus nephritis, and antiphospholipid syndrome increase the risk for pregnancy loss by twofold to fourfold.

Preterm birth, defined as a birth before 37 weeks' gestation, occurs in about one-third of SLE pregnancies (Figure 39-2). Among live births, the meta-analysis found that 39.4% of deliveries were preterm.⁷ The cause of preterm birth in the majority of these pregnancies has not been well quantified, but it is frequently induced because of maternal SLE disease activity, preeclampsia, slow fetal growth, or fetal distress. Spontaneous preterm birth, either prompted by contractions and preterm labor or premature rupture of membranes, is also increased in SLE. In one carefully collected prospective cohort of SLE pregnancies, half of the pregnancies that survived past 23 weeks' gestation delivered preterm. Among these 33 preterm deliveries, 13 (39%) were due to premature rupture of membranes compared with 18% in a control population of preterm births ($P = .001$).⁸ The main predictor of preterm birth in women with SLE is increased disease activity during pregnancy.

Preeclampsia is the syndrome of hypertension and proteinuria that occurs in the second half of pregnancy and resolves postpartum. The etiology is not entirely understood, but the current main hypothesis is that impaired trophoblast invasion of the uterus early in pregnancy results in poor development of the spiral arteries that deliver blood

Figure 39-2 Preterm birth (delivery before 37 weeks' gestation among live births) is increased in most prospective pregnancy cohorts.^{7,11,15-18}

from the mother, through the placenta, and to the fetus. Later in pregnancies, these arteries are not able to expand to provide sufficient blood flow to the fetus, resulting in a cascade of endocrine, inflammatory, and endothelial changes that promotes maternal hypertension and proteinuria.⁹ In the general population, preeclampsia typically occurs in 5% to 8% of pregnancies and only 1/10 of these present before 34 weeks' gestation. The risk for preeclampsia is increased if a woman has previously had preeclampsia, particularly if it occurred early in pregnancy and was severe (blood pressure over 160/110, proteinuria over 5 g/24 hr, or other severe organ manifestations). Also at risk are first pregnancies and pregnancies in women with obesity, diabetes, hypertension, age older than 40, and a family history of preeclampsia.⁹ Up to one quarter of pregnancies in women with SLE are complicated by either hypertension or preeclampsia.¹⁰ In a meta-analysis of SLE pregnancies, 7.4% reported preeclampsia, but the rate varied greatly between studies.⁷ Preeclampsia can be difficult to distinguish from active lupus nephritis. Other signs of SLE activity including arthritis, rash, low complement, or rising double-stranded deoxyribonucleic acid (dsDNA)-titer can help determine the etiology of hypertension and proteinuria. Treatment of these two conditions is different: immunosuppression for SLE and delivery for preeclampsia. In some situations, treatment for both is prudent and the ultimate determination of cause will be possible postpartum either through resolution of preeclampsia over the first month after delivery or renal biopsy for persistent disease.

Placental insufficiency, which leads to less blood and nutrient flow to the developing fetus, can lead to small babies. Definitions of this vary, but it can be measured both in utero via ultrasound and at birth by birth weight and is typically defined as a baby weighing less than the 10th percentile of expected weight for gestational age. In the meta-analysis of SLE pregnancies, 12.7% of babies were noted to be small. In an analysis of the Nationwide Inpatient Sample, which includes data for 20% of all deliveries in the United States, 5.6% of pregnancies in women with SLE were identified as intrauterine growth restricted, a rate that was 2.6-fold higher than for other pregnancies in the United States ($P < .01$).¹⁰ In the Hopkins Lupus Cohort, 23% of all live births weighed less than the 10th percentile for gestational age of delivery.¹¹

Although up to 30% of women with SLE will have a flare during pregnancy, the majority of these are fairly mild and readily controlled.^{7,11} Several studies in the 1980s and 1990s tried to determine whether SLE worsens with pregnancy, but the conclusions were often conflicting. It seems that many patients will proceed through pregnancy without difficulty, but an important minority will suffer significant disease activity that can harm both the pregnancy and the woman's own health and survival.

Significant SLE activity is associated with increased pregnancy loss and preterm birth. The degree of SLE activity is important—it appears that mild activity of the skin or joints will have minimal impact on pregnancy outcomes. Internal organ involvement including the kidneys, hematologic cell lines, serositis, and the central nervous system (CNS) is more highly associated with pregnancy morbidity. Women with highly active SLE around the time of conception have an estimated 40% risk of pregnancy loss.^{11,12} This

applies to women with high overall disease activity, with isolated proteinuria greater than 500 mg/24 hr, or isolated thrombocytopenia.¹² Disease activity in the second and third trimesters is less often associated with pregnancy loss but can double the rate of preterm delivery.¹¹

The most important predictors of SLE activity in pregnancy are increased SLE activity in the 6 months before conception, the frequency of SLE flare in the years before pregnancy, and the cessation of immunosuppressive medications. Among women with high-activity SLE in the 6 months before conception, 58% had high-activity SLE during pregnancy. On the other hand, of women with relatively quiet SLE before pregnancy, only 8% had high activity in pregnancy.¹¹ The cessation of hydroxychloroquine (HCQ) before or concurrent with conception is associated with a high rate of SLE flare, particularly in the second and third trimesters. Because these flares are predominantly in the skin and joints or manifest as fatigue, they do not have a statistically significant impact on pregnancy outcomes. They can, however, lead to significant discomfort and the use of higher doses of corticosteroids during pregnancy. Stopping immunosuppressants including mycophenolate mofetil or azathioprine because of pregnancy may lead to a flaring of SLE activity, particularly renal or hematologic, that could lead to significant pregnancy morbidity. For this reason, women who require these drugs to maintain quiet SLE activity before pregnancy will likely benefit from continuing azathioprine during pregnancy (see further discussion in [Medications in Pregnancy and Lactation](#) later).

Lupus nephritis, whether active or quiescent during pregnancy, affects pregnancy outcomes. Several prospective studies of lupus nephritis in pregnancy document that women with prior lupus nephritis have a higher rate of pregnancy loss, preterm birth, and preeclampsia than other women with and without SLE. Active lupus nephritis during pregnancy increases the pregnancy loss and preterm birth rates by twofold to threefold.^{13,14} Renal failure is a rare complication of active lupus nephritis in pregnancy.

Maternal death is 20-fold more common among SLE pregnancies than other pregnancies, but it is fortunately rare.⁸ When compared with the annual risk of death in all women with SLE (ranging between 0.5% and 1% of all women, depending on the study sample), the risk of death in pregnancy for women with SLE is lower (0.3%).⁸ This is likely because women with the most severe SLE, who are at the highest risk for death, avoid pregnancy. Reported causes of maternal death in women with SLE include thrombosis, in particular pulmonary embolism, and infection. Although risk factors for maternal death have not been studied due to the rarity of this event, patients at higher risk for death include those with prior major thrombosis; severe pulmonary hypertension, lung, or renal disease; and women requiring high-dose immunosuppression.

Several simple interventions can be employed to decrease the likelihood of fetal and maternal morbidity:

1. Time pregnancy to coincide with periods of disease quiescence. At least 6 months of quiet SLE is required to decrease the risk of disease flare and adverse pregnancy outcomes. Accomplishing this requires discussing and prescribing effective contraception to women with significant SLE activity to avoid conception. Active SLE does not impair fertility.

2. Avoid teratogenic medications, but continue immunosuppression when needed. The adverse effects of highly active SLE generally outweigh the teratogenic effects of many SLE medications. Women taking HCQ before conception should continue this drug to avoid an SLE flare. Women who are taking mycophenolate mofetil or cyclophosphamide to control SLE activity should either avoid pregnancy or switch to azathioprine before pregnancy (or when pregnancy is discovered). Discontinue angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), but continue blood pressure control with calcium channel blockers and labetalol.
3. Use prednisone to treat SLE flare, but do not use prophylactically in a woman with quiet disease.
4. Start women with SLE on low-dose aspirin (81 or 100 mg a day) to decrease the risk of maternal thrombosis, preeclampsia, and preterm delivery.
5. Have all women followed by, or at least seen in consultation by, a high-risk obstetrician (also called maternal-fetal medicine).
6. Continue close rheumatology follow-up for women with SLE during pregnancy. Do not assume that the obstetrician will continue to monitor for or will be able to identify SLE activity.

RHEUMATOID ARTHRITIS

RA is a systemic, autoimmune disease that leads to chronic inflammation of the joints and other structures. Without use of disease-modifying agents, RA often leads to progressive deformities of the hands, feet, and larger joints. Over the past few decades, improved therapies have led to better control of disease and significantly slower progression of joint damage. With better control of short-term and long-term effects of the disease, people with RA may be more apt to consider childbearing and childrearing than in previous decades.

RA is a female-predominant disease, affecting women more than men in a 3:1 ratio. The prevalence of RA in the United States is approximately 1.4% with a median age of onset of 59 years. The prevalence of women of childbearing age in the United Kingdom (data on prevalence in the United States are not available) is estimated to be 1 to 2/1000 of women between ages 16 and 44.¹⁹ A recent study estimated that approximately 1400 women with RA gave birth in the United States in 2002.^{20,21}

Fertility

Although it has been apparent for many decades that women with RA tend to have fewer children or are more likely to be nulliparous than control populations, there is a paucity of data looking at RA associated with fertility. Katz²² studied pregnancy patterns and decisions regarding childbearing in a group of 411 women with RA in 1999. Results showed that family sizes were smaller among women who developed RA before having any children or to completing childbearing. Approximately 30% of respondents who developed RA during the childbearing years reported that the diagnosis affected their decision to have additional children, and 12% reported being advised by a provider to limit

family size. From these data, it appears that reduced numbers of children among women with RA may be related to choice rather than to reduced fertility or increased pregnancy loss.²² Reduced sexual activity due to functional limitations from the disease are a further, nonbiologic cause of lower birth rates due to reduced opportunity for conception.²³

Although several disease-modifying antirheumatic drugs (DMARDs) may assert teratogenic effects on the fetus,²⁴ and nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with temporal and reversible infertility,²⁵ most chronic medications taken to manage inflammatory arthritides have no known adverse effect on hormonal, ovarian, or endometrial function. Several studies have found that estrogen-containing oral contraceptives yield a protective effect or mildly ameliorating effect on RA, and increased use of oral contraceptive pills among women with RA may further contribute to lower birth rates. These medication issues are easily overcome in women with RA who desire a pregnancy. However, it is much more difficult to formally study biologic infertility in this population. Few studies have been able to disentangle true inability to conceive a child from the myriad of other reasons for which women with RA may have fewer pregnancies. There has been a suggestion of reduced ovulatory function among women with RA in a small study of menstruating women,²⁶ but this has yet to be followed up with larger studies. A recent population-based study from Norway has found that women with RA used assisted reproduction technologies more than age-matched healthy women.²⁷ Similar findings were seen in a case-control study of pregnant women in the Netherlands (17.8% RA patients used assisted reproductive techniques compared with 3% in healthy women).²⁸

Pregnancy Outcomes

In the absence of exposure to potentially teratogenic medications (including methotrexate, leflunomide, and mycophenolate mofetil [MMF]), earlier observations showed that maternal-fetal outcomes did not appear to be changed by maternal RA.²⁰ However, more recent studies have shown that there are, in fact, some differences in these outcomes comparing women with RA with the general population. Several recently published population-based studies have documented an increased risk of preterm birth (<37 weeks' gestational age) and small for gestational age (SGA, <10th percentile weight for gestational age) among women with RA compared with healthy women (Table 39-1). Although the odds ratios are generally less than 2.0, the consistency of reports over several different populations suggests a true association between a diagnosis of RA and adverse fetal outcomes. Because most of these studies are population based, relying on administrative data, they do not contain data regarding medication use or disease activity before conception or during gestation. Two prospective cohort studies of pregnant women with RA compared with healthy pregnant women have demonstrated an inverse association between disease activity during the third trimester of pregnancy and birth weight.^{28,29} One study from the Netherlands found a linear relationship between third-trimester disease activity (assessed by a modified DAS28-CRP) and birthweight in a multivariate model that adjusted for gestational

Table 39-1 Odds Ratios of Preterm Delivery and Small for Gestational Age Infants among Women with Rheumatoid Arthritis Compared with Healthy Controls in Population-Based Studies

CI, confidence interval; OR, odds ratio.

age, maternal smoking, maternal age, education, parity, and prednisone use.²⁸ A second study, from the United Kingdom, found that women with active disease during the third trimester had lower birth weight than women with RA in remission; women with inactive RA had birth outcomes indistinguishable from healthy control women.²⁹ Together, these data suggest that RA is associated with higher risks of preterm delivery and lower birth weight infants; however, this may be mitigated by achieving good control of disease activity during at least the third trimester of pregnancy.

Disease Outcomes

Since the initial report by Hench in 1938,³³ it has been thought that RA disease activity improves during pregnancy. In reviewing the majority of the data looking at disease activity during pregnancy, it appears that approximately 75% of patients will have some degree of improvement.^{34,35} This may occur as early as the first trimester and continue through the end of pregnancy. The exact underlying immunologic mechanism as to why this occurs is unclear. However, more recent reports have suggested that this improvement is actually not as dramatic as was once perceived. De Man and colleagues looked prospectively at 84 patients with RA and determined improvement and deterioration by the DAS28 changes.³⁶ For women who started the pregnancy with moderate disease activity, only 48% had a moderate improvement response. Those with low disease activity during the first trimester tended to remain stable. Only 27% of the patients as a whole were in remission by the third trimester. In comparison, Barrett³⁷ and Nelson and colleagues³⁵ in previous studies showed that 16% and 39%, respectively, were in remission during the third trimester (though different definitions of remission were used). Unfortunately, no clinical or laboratory predictors have been found to reliably predict the disease course during pregnancy. Conflicting reports have been published looking at the degree of maternal-fetal human leukocyte antigen (HLA) class II mismatch and maternal RA disease activity.^{35,37,40} The majority of studies have confirmed that a higher degree of maternal-fetal HLA mismatch is associated with improved disease activity during pregnancy^{35,38,39}; however, a study of 110 maternal-fetal pairs failed to find such an association.⁴⁰ More recently, a prospective study of 118 pregnant women with RA from the Netherlands found that women who were seronegative for rheumatoid factor or anticyclic citrullinated peptide had a greater likelihood of improvement in disease activity during pregnancy.⁴¹ This has yet to be studied in other populations.

Despite a wide range of disease activity during pregnancy, the majority of studies have shown that RA may worsen or flare in the postpartum period.^{34,36,37,41} In addition, a recent study has demonstrated an increase in the incidence of RA during the first 24 months following delivery compared with 25 to 48 weeks' postpartum among premenopausal women in Norway,⁴² suggesting that either the incidence of RA peaks in the postpartum months or pregnancy may delay the onset of RA in susceptible individuals.

Ways to Improve Outcomes

Monitoring disease activity during pregnancy can be tricky because distinguishing underlying activity of RA from normal changes during pregnancy is often not clear. Both erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are markers of systemic inflammation that are often used to follow disease activity in rheumatic disease. Unfortunately, both these levels can fluctuate in pregnancy with more dramatic increases seen in ESR rather than CRP.³⁶ Therefore these levels must be interpreted with caution in women with RA. Furthermore, clinical changes of pregnancy such as fatigue, swelling (especially of the distal extremities), and carpal tunnel syndrome are commonly seen in pregnancy. Careful examination of the wrist and assessment of neurologic symptoms are important to distinguish carpal tunnel syndrome from RA flare.

Given the growing evidence that active disease during pregnancy is associated with increased risks of adverse fetal outcomes, it is important to achieve control of disease activity before conception and during pregnancy whenever possible. In the ideal situation, women with RA considering pregnancy should aim to achieve good control of disease after discontinuation of medications with teratogenic potential, using medications considered safer during pregnancy if necessary to reduce inflammation. Determining the right medications for a pregnant patient can be challenging and requires an individualized approach. Certain medications are strictly contraindicated during pregnancy and should always be avoided due to teratogenic potential: methotrexate and leflunomide. Additionally, these agents should be discontinued immediately on the discovery of pregnancy in a woman receiving these medications (leflunomide will require an additional washout with cholestyramine).⁴³ If a disease-modifying agent is required to control chronically active disease during an anticipated or confirmed pregnancy, plaquenil, sulfasalazine (SSZ), and/or azathioprine carry the fewest risks to the developing fetus.

and are generally considered relatively safe.⁴⁴ However, these agents may have limited efficacy for moderate to severely active disease and may be insufficient to control disease during pregnancy. The use or continuation of anti-tumor necrosis factor (TNF) agents during pregnancy has been more controversial. Some studies have suggested an increased risk for congenital abnormalities, whereas others have not.⁴⁵ Cumulatively, the data seem to show that exposure to anti-TNF agents in pregnancy does not seem to increase risk of miscarriage, preterm delivery, or congenital malformations.⁴⁶ In cases of severe inflammatory disease before or during pregnancy, TNF inhibitors may be used with caution, provided that the mother is aware of and comfortable with the risk-to-benefit ratio.

For acute flares of disease, use of glucocorticosteroids is the best option because they have a rapid onset of action and can be titrated to the level of disease activity. There is vast experience with glucocorticoids during pregnancy for many indications. Prednisone is perhaps the most ideal choice for the treatment of maternal disease because a very small amount of active drug will enter the fetal circulation.⁴⁴ In fact, some women may even require regular glucocorticoid use if background DMARD therapy is ineffective. The goal should always be to minimize the dose as best as possible and to prescribe adequate calcium and vitamin D supplementation during use. Isolated joints may be best managed through direct local injection of steroids, thus avoiding significant systemic exposure to the drug. Although intermittent NSAID use appears to be safe, there are some risks to regular use, particularly during the latter half of pregnancy because it can be associated with premature closure of the ductus arteriosus.⁴⁴

SCLERODERMA

The hallmarks of scleroderma, vasculopathy and fibrosis, complicate surprisingly few numbers of pregnancies in women with this disease. Pregnancies are relatively rare in women with scleroderma, primarily because the onset of the disease is often after a woman has completed her family. About 200 pregnancies in women with scleroderma have been reported in the literature, however, with largely good results. The rate of miscarriage is about 15%, which is 50% higher than in the general population.⁴⁷ Stillbirths, however, are rare. Preterm birth rates range from 25% to 40%, dependent on the degree of internal organ damage.⁴⁷ Reports of preeclampsia are rare, but in a nationwide database of pregnancies, 23% of the 504 with scleroderma had hypertensive complications, including preeclampsia.⁴⁸

To maintain pregnancy, a woman's body must make major hemodynamic changes including an increase in blood volume of 50%, increase in cardiac output, and decreased vascular resistance.⁴⁹ These adaptations may be hindered by underlying vasculopathy in women with scleroderma. Pulmonary hypertension, in particular, can both limit pregnancy success and put the woman at significant risk for death from hemodynamic collapse. Pregnancy in a woman with pulmonary hypertension carries a maternal mortality rate of 17% to 33% with deaths caused primarily by right ventricular failure or pulmonary embolism.⁵⁰ The risk for death is greatest around the time of delivery and in the

weeks postpartum. Neonatal or fetal death after 22 weeks' gestation occurred in 7% to 13% of pregnancies complicated by pulmonary hypertension, about one-third had intrauterine growth restriction, and more than 85% delivered preterm.⁵⁰ Medical treatment of pulmonary hypertension may include prostacyclin, nitric oxide, and calcium channel blockers. Due to the high maternal and fetal morbidity and mortality, pulmonary hypertension is considered a contraindication to pregnancy.⁵⁰

Scleroderma renal crisis, though rare in pregnancy (occurring in 2% to 3% of scleroderma pregnancies), can be catastrophic.⁴⁷ It can be difficult to distinguish from preeclampsia, both presenting with hypertension, proteinuria, and in severe cases hemolysis and thrombocytopenia. Women at particular risk for this complication include those with a prior history of it and those with recent onset of rapidly progressive diffuse disease. If the pregnancy is near term, delivery followed by aggressive ACE inhibitor therapy is indicated. If not near term, treatment with ACE inhibitors should be weighed. These drugs carry significant risk for permanent and fatal renal disease in the fetus but are also the essential treatment for scleroderma renal crisis.⁴⁷

Gastroesophageal reflux disease often worsens in pregnancy. Raynaud's phenomenon, however, often improves due to decreased vascular resistance.⁴⁷ Skin disease does not seem to change significantly in pregnancy.⁴⁷ The peripheral edema of pregnancy may be particularly uncomfortable, however, for women with diffuse scleroderma.

An approach to improving pregnancy outcomes in women with scleroderma begins with careful preconception counseling and continues with close monitoring during pregnancy.

1. Women with pulmonary hypertension, a history of scleroderma renal crisis, or severe interstitial lung disease should be made aware of the significant risk to their life, health, and the survival of a pregnancy due to their disease.
2. Women without known pulmonary hypertension should undergo screening with an echocardiogram and pulmonary function testing before or early in pregnancy to identify previously subclinical disease.
3. Women taking ACE inhibitors or angiotensin-receptor blockers should discontinue these prior to pregnancy, if possible.
4. Due to the high risk of preterm birth and preeclampsia, a daily dose of low-dose aspirin should be considered.
5. Women with scleroderma should be followed closely in pregnancy by rheumatology and a high-risk obstetrical team. In addition, cardiology or pulmonologists may need to be involved on the basis of the degree of cardiopulmonary disease.
6. Repeated screening for intrauterine growth restriction should be performed in the third trimester.

PSORIATIC ARTHRITIS

Psoriatic arthritis (PsA) is a chronic destructive autoimmune arthropathy often associated with the presence of psoriasis. Psoriasis is a chronic inflammatory skin condition

manifested by hypertrophic erythematous plaques with overlying scale that can be quite disfiguring and functionally limiting for affected patients. Both psoriasis and PsA affect men and women equally; the average age of onset of psoriasis is in the second and third decades with PsA often occurring approximately 10 years later among the 20% who will go on to develop PsA.⁵¹

Pregnancy and Disease Outcomes

Outcomes data for women with PsA are scarce⁵²; however, preconception counseling for patients with these conditions is similar to those with RA. They should have a good understanding of drug toxicities, side effects, and benefits of use as detailed earlier. In addition, it appears as though women can expect some degree of improvement in their arthritis symptoms during pregnancy. At least half of women show some resolution of their arthritis in case series reported to date.^{53,54} However, the degree of improvement has not yet been elucidated because more recent data reviewing pregnant PsA cohorts have not occurred. Furthermore, most case series and reports of pregnancy in PsA have occurred before the use of biologics and the era of better disease control, so it is difficult to say with certainty if these women actually clinically improve during as opposed to before pregnancy. As in RA, a postpartum flare often occurs within 3 months.⁵³ Studies looking at pregnancy and fetal outcomes appear to show no increase in premature labor, preeclampsia, or adverse fetal outcomes.^{53,54}

Ways to Improve Outcomes

Management of the arthritis in PsA during pregnancy is similar to that of RA. NSAID use sparingly, corticosteroids at low dose, and DMARDs that are not fetal toxic such as SSZ may be good options. Plaquenil is generally not commonly used in patients with PsA due to the thought that it may increase flares in skin disease. Similarly, corticosteroids may be relatively contraindicated in some patients with profound cutaneous disease. As with other conditions, it is important to discontinue potentially teratogenic medications including methotrexate and leflunomide before conception. The use of TNF inhibitors may be considered in cases of severe disease where the benefits of improved control of disease outweigh potential risks associated with antenatal exposure.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) is a chronic autoimmune disease that most often affects the axial skeleton, as well as the hips and shoulders, that is often, but not always, associated with the HLA-B27 allele. In contrast to most autoimmune diseases, AS displays a male predominance in a ratio of 4:1. The overall prevalence of disease in Caucasian populations is approximately 0.03% to 0.1%.⁵⁵ Prevalence estimates in women of childbearing age are not available, but the incidence in Rochester, Minnesota, is 3.6 to 6.4 cases per 100,000 person-years.⁵⁶ Treatment options for AS are much more limited than for RA, and most therapies do not appear to abrogate the progressive spinal fusion that is characteristic of the disease. Because of the relatively low

incidence of AS in women of childbearing potential, data regarding pregnancy experiences in this population are sparse.

Pregnancy Outcomes

Unlike SLE and RA, underlying maternal AS does not appear to be associated with increased risks of maternal or fetal morbidity. A questionnaire-based study of 649 women with AS in North America and Europe⁵⁷ was performed looking at pregnancy outcomes. It was found that 15.1% ended with miscarriage, a rate not dissimilar to the general population. The overwhelming majority (93.2%) of cases delivered at term, but 58% delivered by cesarean section with AS, rather than other pregnancy-related conditions, as the stated indication. Neonates were healthy with a mean birth weight of 3339 g. Studies looking at pregnancy and fetal outcomes appear to show no increase in premature labor, preeclampsia, or adverse fetal outcomes.

Disease Outcomes

Most women with AS who become pregnant either remain stable or may have some clinical worsening of symptoms during the course of pregnancy. In addition, at least half will have some aggravation of symptoms in the postpartum period as well.^{54,57-59} In Ostensen and Husby's questionnaire-based study of pregnancy in AS, disease activity during pregnancy was reported as unchanged in 33.2%, improved in 30.9% (which correlated with a history of peripheral arthritis), and worsened in 32.5% (which was mostly increased low back pain/hip pain after week 20). Sixty percent had a postpartum flare within 6 months after delivery.⁵⁷ In a smaller study of nine patients with AS followed prospectively during pregnancy with validated disease activity measures (BASDAI scores, morning stiffness, patient global assessment), the majority had active disease during pregnancy, four had a decrease of 20% during pregnancy, and no remissions were found. Furthermore, women with AS had high pain scores throughout pregnancy when compared with women with RA, with resultant increased utilization of NSAIDs and paracetamol.⁶⁰

Special considerations specific to AS should be considered. Bone loss is a well-recognized feature in AS. Osteoporosis is common and is largely related to disease activity, whereas vertebral fractures appear to be related to duration of disease and structural severity of the disease.⁶¹ The prevalence of vertebral fractures has been reported but variable.⁶² Cooper and colleagues reported an increased odds ratio of 7.7 (4.3 to 12.6).⁶³ These fractures are often spontaneous, low-trauma fractures. Pregnancy can also lead to osteoporosis and/or bone density loss, which most often occurs in the lumbar spine in the peripartum period or within a few months after the birth of a child. Bone density loss related to pregnancy in combination with underlying bone density loss or loss of integrity due to AS may increase the risk of fracture even further and has been reported.^{64,65} This bone fragility should especially be considered during delivery when tremendous intrauterine pressure, most of which is transmitted to the perineum and lumbar spine, is created during active labor and pushing. If a patient has severe osteoporosis and/or poor spinal mobility, an elective

cesarean section may be considered to reduce risks associated with active labor.

Ways to Improve Outcomes

Management of AS during pregnancy is similar to that of RA. However, data regarding the relationship between active disease and adverse pregnancy outcomes are scarce due to fewer numbers of pregnant patients who have been studied. NSAIDs should be used as needed to improve function, but use should be limited or discontinued in the third trimester. Corticosteroids at low dose and DMARDs such as SSZ may be good options to treat peripheral disease but do not have much utility in treating axial symptoms. Use of anti-TNF therapy during pregnancy remains controversial at this point and should be used only with caution in the absence of more definitive data regarding pregnancy outcomes.

The mechanical variants that result in patients with AS are important to consider during delivery. AS often results in inflammation of and/or fusion of the pubic symphysis or sacroiliac (SI) joints. Hormones released during pregnancy such as relaxin cause the symphysis pubis and SI joints to soften and separate to some degree to prepare for the birthing process. For example, the nonpregnant gap of the pubic symphysis is 4 to 5 mm but in every pregnancy there will be an increase in 2 to 3 mm. If fusion interferes in adequate separation, it can create a mechanical obstacle during labor and delivery. In some cases, this may cause increased pain and/or lead to need for cesarean section delivery as opposed to vaginal birth. As noted earlier, Ostensen and colleagues reported that, compared with healthy women, cesarean section was more frequently performed in patients with AS and in 58% of the cases AS was the indication for cesarean delivery.⁵⁷ Aside from potential difficulties with labor mechanics, these ligament and/or joint changes in the setting of underlying inflammation may worsen pain symptoms and increase SI joint or pubic symphysis dysfunction (a disorder common in healthy pregnant women).

VASCULITIS

The data on pregnancy in women with vasculitis are limited to case reports and case series. Because of the dearth of reliable scientific data, many of our assumptions about the treatment of vasculitis in pregnancy are based on the principles we have learned about pregnancy in other systemic autoimmune diseases. Based on this, we assume that having significant vasculitis activity, particularly in the kidneys or lungs, is associated with poor pregnancy outcomes.

Takayasu's Arteritis

Takayasu's arteritis, a large vessel vasculitis that leads to stenoses and aneurysms in the aorta and its branches, primarily affects young women. More than 150 pregnancies in women with Takayasu's arteritis have been published, most coming from five case series.⁶⁶⁻⁷⁰ The primary complication seen in these pregnancies was hypertension ($\leq 30\%$ of pregnancies) with almost 20% developing preeclampsia.⁷¹ Serious maternal complications including myocardial infarction, aortic aneurysm and rupture, renal insufficiency,

and pulmonary embolism have been reported, but the majority of women appear to do well without progression of Takayasu's arteritis during pregnancy. More than 80% of pregnancies resulted in the delivery of a healthy baby, though preterm delivery, either spontaneous or induced for preeclampsia, was common. Intrauterine fetal demise was reported in 8% of pregnancies, and intrauterine growth restriction (a marker of poor placental perfusion) occurred in almost 20% of pregnancies.⁷¹

Treatment of Takayasu's arteritis during pregnancy depends on the current symptoms of the disease. If active inflammation is present, leading to arterial damage, treatment with corticosteroids or immunosuppressants with a low teratogenic risk may be reasonable. Among asymptomatic women, these medications may not be necessary during pregnancy and should not be started prophylactically. Close monitoring of blood pressure is essential during pregnancy, and treatment with acceptable antihypertensives will likely promote good placental health and minimize maternal organ damage. Blood pressure can increase significantly during labor, exacerbated by maternal exertion. It is important to keep in mind that maternal blood pressure measurements may be inaccurate with an arm cuff if subclavian stenosis is present. In these cases, internal blood pressure monitoring and/or avoidance of labor via a scheduled cesarean section may be prudent.

Small Vessel Vasculitis

Granulomatosis with polyangiitis (formerly Wegener's granulomatosis), microscopic polyangiitis, and Churg-Strauss vasculitis are all rare small vessel vasculitides with a peak onset after the reproductive years. In addition, the primary treatment for severe disease includes cyclophosphamide, which leaves many women infertile. For these reasons, there are few systematically collected data on pregnancies in these diseases. A recent review of 20 pregnancies in 12 women with systemic necrotizing vasculitis (including WG, CSS, PAN, and MPA) from several centers in France included 2 elective abortions, 4 miscarriages, and 14 live births, half of which were delivered preterm. Complications included isolated episodes of pancreatic artery microaneurysms, transient cardiac failure, renal insufficiency from thrombotic microangiopathy, and severe pneumonia. Vasculitis remained quiescent in most pregnancies.⁷² Case reports of small vessel vasculitis in pregnancy are similar with relatively good pregnancy outcomes. Several report the onset of vasculitis during pregnancy.

The principles of treatment of these vasculitides are similar to other systemic rheumatologic disease: Increased disease activity is likely related to poor pregnancy outcomes, so maintenance of quiet disease is important. Continuation of low-dose prednisone and azathioprine seems prudent in women with recently active disease, but these medications do not need to be initiated prophylactically in women who have been in remission.

Behçet's Disease

Behçet's disease, which primarily manifests with oral and genital ulcers but can also involve ocular or CNS disease and arterial or venous thrombosis, is a rare disease with

limited pregnancy data. Case series are contradictory about the course of disease activity, with some reporting improvement and others worsening during pregnancy. Pregnancy outcomes are largely good, but some women have increased numbers of miscarriages and episodes of hypertension.⁷³ Pregnancy is a period of hypercoagulability, so prophylactic treatment with low-molecular-weight (LMW) heparin for women with a history of thrombosis is important.

ANTIPHOSPHOLIPID ANTIBODIES AND THE ANTIPHOSPHOLIPID ANTIBODY SYNDROME

The antiphospholipid antibody syndrome (APS) is discussed in detail in Chapter 82. However, the APS, albeit primary or secondary in women with other autoimmune diseases, has important implications for women who are considering pregnancy. In some cases, the clinical manifestations of the syndrome are limited to the obstetric realm. The revised 2006 criteria for the APS include (1) laboratory criteria: lupus anticoagulant, anticardiolipin antibodies, or anti- β_2 glycoprotein I positive on two or more occasions at least 12 weeks apart; (2) vascular thromboses: at least one unequivocal episode of arterial, venous, or small vessel thrombosis; and (3) obstetric criteria: one or more unexplained deaths of a morphologically healthy fetus after 10 weeks' gestational age; one or more births before 34 weeks' gestation because of preeclampsia or placental insufficiency; or three or more consecutive spontaneous abortions (before 10 weeks' gestation) without chromosomal, anatomic, hormonal, or other causes to explain pregnancy loss.⁷⁴ The prevalence of lupus anticoagulant or antiphospholipid antibodies in the general population is unknown, but it is estimated that up to 8.5% of the general obstetric population has positive antibodies.⁷⁵ However, it is important to recognize that the mere presence of antibodies/lupus anticoagulant does not in itself confer an increased risk of thromboses/obstetric complications, and actual clinical events are required to make a diagnosis of the actual syndrome. For example, only about 40% of SLE patients with positive titers for antiphospholipid antibodies will develop thrombotic events, even though SLE patients have a high prevalence of antibodies.⁷⁶ When thinking about pregnancy outcomes among women with antiphospholipid antibodies or the antiphospholipid antibody syndrome, it is helpful to divide women into three general categories: (1) women with APS and a history of arterial/venous thrombotic events; (2) women with APS with clinical manifestations limited to obstetric complications (no maternal thrombotic events); and (3) asymptomatic women found to have positive tests for lupus anticoagulant and/or antiphospholipid antibodies (no history of adverse pregnancy outcomes or maternal thromboses).⁷⁷

Antiphospholipid Antibody Syndrome with Thrombotic Manifestations

As is evident in the nonpregnant population of APS patients with a history of arterial or venous thromboses, there is a high rate of recurrent thromboses and lifelong anticoagulant therapy is the mainstay of treatment.⁷⁶ In nonpregnant

patients, this is usually achieved with the use of warfarin to a target international normalized ratio (INR) of 2.0 to 3.0. In some cases, recurrent thromboses recur despite therapeutic levels of warfarin and these patients may need to be managed with a higher target INR of 3.0 to 4.0, long-term therapy with heparin, or combination antithrombotic agents.⁷⁶

When women with APS and thrombotic manifestations consider pregnancy, aggressive antithrombotic therapy with LMW heparin must be continued to reduce risks of recurrent maternal thromboses during the increased hypercoagulable state of pregnancy and the postpartum period. In addition, studies have suggested that women with thrombotic manifestations have higher risks of adverse pregnancy outcomes than do women with only obstetric manifestations of APS despite using the more aggressive antithrombotic management protocol with low-dose aspirin and LMW heparin (daily heparin dosing for obstetric APS compared with twice-daily dosing for thrombotic APS patients).⁷⁷ Overall, with appropriate antithrombotic prophylaxis and management, live-birth rates are greater than 70%.⁷⁶ At this time, there is no role for prednisone or other immunosuppressive treatment in the prevention of thrombotic or obstetric complications due to APS.

Antiphospholipid Syndrome with Obstetric Manifestations

Optimal management of pregnancy in women who meet obstetric criteria for APS has been the subject of several randomized clinical trials and meta-analyses; unfortunately, some controversy remains regarding the optimal treatment regimen.⁷⁶ Two randomized controlled studies found a significant reduction in pregnancy loss in women treated with unfractionated heparin plus aspirin when compared with aspirin alone.^{78,79} Other trials, comparing LMW heparin plus aspirin to aspirin alone, did not find a difference in live-birth rates.^{80,81} Studies that have evaluated the difference between LMW or unfractionated heparin (plus aspirin) have failed to find a difference in outcomes.^{82,83} A recent meta-analysis of heparin plus aspirin compared with aspirin alone has concluded that heparin (LMW or unfractionated) plus aspirin has a 30% increase in live-birth rate compared with aspirin alone.⁸⁴ Experts generally agree that low-dose aspirin should be instituted in the preconceptional period, with the addition of once-daily subcutaneous heparin (LMW or unfractionated) on confirmation of pregnancy.^{76,77} Newer experimental evidence strongly suggests a critical role of tissue factor and activated complement in APS-mediated pregnancy loss.⁸⁵ Inhibitors of these factors have yet to be studied in the clinical setting.

Antiphospholipid Antibodies or Lupus Anticoagulant without a History of Clinical or Obstetric Events

Although the presence of lupus anticoagulant or antiphospholipid antibodies is associated with increased risks of adverse pregnancy outcomes, there is currently no way to predict which asymptomatic seropositive women will go on to develop related obstetric complications in the absence of a prior history of a clinical event. Thus randomized

controlled trials or risk-benefit analyses of primary prophylaxis during pregnancy are not available. This can be particularly troubling in primigravidas with known positive antibodies because outcomes of previous pregnancies cannot be used to predict the course of a current or future pregnancy. In these cases, the risk of bleeding associated with use of heparin and aspirin is not offset by a theoretic improvement in pregnancy outcomes. Many practitioners elect to use low-dose aspirin alone in these situations, although there are no data to support this practice. In subjects with SLE and asymptomatic antiphospholipid antibodies, the use of HCQ before and during pregnancy may be considered because HCQ may have some antithrombotic properties by several different mechanisms.⁸⁵ Again, no clinical data are available to support the routine use of HCQ in pregnant women for the purpose of reducing the risk of APS-related obstetric complications.

MEDICATIONS IN PREGNANCY AND LACTATION

The decision to use medications in pregnancy must always balance the risks and benefits to both mother and fetus. For some more systemic rheumatologic diseases, in particular SLE, the risk to the pregnancy of active SLE outweighs the risks of many medications. For other more limited diseases such as RA, the disease process has limited impact on the fetus, making medications more optional.

The U.S. Food and Drug Administration (FDA) rates each medication on the basis of its potential risk to the fetus (Table 39-2). Although this system can provide some general guidance, it is not a perfect system by which to treat a patient. For example, azathioprine and MMF are both FDA class D immunosuppressants, but current data indicate that azathioprine is probably far safer for a fetus than MMF. The FDA has plans to replace the current grading system with more objective data, but when this change will occur is unclear.

Breast-feeding is generally believed to be beneficial to both mother and infant in the best of circumstances. Some rheumatologic medications may transfer into breast milk to a degree that is potentially dangerous, whereas others have more limited transfer. Although current information on lactation and medications is included in this chapter (see Table 39-2), continually updated information is available from the Texas Tech University Infant Risk website at www.infantrisk.org/.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are classified by the FDA as C, with possible risks in the first and second trimesters, but D in the third trimester with well-defined risks.

Some evidence indicates that frequent use of NSAIDs in the week of conception can increase the risk for miscarriage. In a case-control study based on pregnant women in the Kaiser hospital-system database, those taking NSAIDs around conception and in the first trimester had a 1.8-fold increase in miscarriage. That risk increased to a 5.6-fold risk for women taking the NSAID in the week of conception and to an 8.1-fold risk for those taking daily NSAIDs.⁸⁶ A

similar study from a Danish birth registry found an increased risk for miscarriage, particularly for women who picked up a prescription for NSAIDs in the 6 weeks before the miscarriage (odds ratio [OR], 3.0 to 6.99).⁸⁷ Suppression of prostaglandins by NSAIDs may lead to poor implantation or decreased placental perfusion, both of which can precipitate miscarriage. Avoidance of frequent NSAID use in the first trimester and around the time of conception may be prudent.⁸⁶

Many studies have not found an association between NSAIDs and a higher rate of congenital malformation, preterm birth, or low birth weight.⁸⁷ Several studies, however, have identified a possible link between NSAID use and congenital heart defects.^{88,89}

In the second and third trimesters, NSAID use may decrease fetal renal perfusion, leading to decreased amniotic fluid production and oligohydramnios. This condition is typically reversible with cessation of the drug.

NSAIDs are contraindicated in the third trimester because they can prompt closure of the fetal ductus arteriosus (DA), the channel through which blood bypasses the fetal lungs. In previous years, NSAIDs were used as tocolytic agents to halt premature labor, allowing several elegant studies demonstrating the impact of NSAID use at different points in the third trimester. With exposure before 27 weeks' gestation, the DA is largely unaffected. Between 27 and 34 weeks, however, about half of the fetuses will have constriction of the DA, a finding that is evident within hours of NSAID dosing but reverses within several days.⁹⁰ Preterm infants with third-trimester exposure to indomethacin have a higher rate of necrotizing enterocolitis, intraventricular hemorrhage, and a mild decrease in renal function for several days of life.⁹¹

During lactation, the preferred NSAID is ibuprofen due to its relatively short half-life and low penetration into breast milk. For a woman taking 400 mg of ibuprofen every 6 hours, less than 1 mg of ibuprofen is excreted into the breast milk each day.⁹² This is far lower than the recommended maximum pediatric dose of 40 mg/kg per day.

Corticosteroids

Corticosteroids vary structurally and will affect the mother and fetus differently. Betamethasone and dexamethasone have fluorine at the 9- α position and are not well metabolized by the placenta. They will cross the placenta with direct effects on the fetus. Most other corticosteroids, however, are metabolized in the placenta by 11- β -hydroxysteroid dehydrogenase to inactivated forms, leaving less than 10% of the active drug to reach the fetus.⁹³ If the goal is to treat the mother, prednisone is the most ideal glucocorticoid because a small amount of active drug will enter the fetal circulation. If the goal is to treat the fetus, betamethasone and dexamethasone are better options and are commonly used in women at risk for preterm delivery to reduce the risk of respiratory distress and cerebral hemorrhage in the preterm infant. Some recent reports suggest betamethasone may be preferred to dexamethasone because it may offer better long-term neurodevelopmental outcomes for the fetus.^{94,95}

Corticosteroids carry the risk of elevated blood pressure, steroid-induced hyperglycemia, and osteopenia. These risks

Table 39-2 Frequently Used Rheumatologic Medications in Pregnancy and Lactation

Drug	FDA Pregnancy Classification	Teratogenic Risks	Other Pregnancy Issues	Lactation
NSAIDs	C (first and second trimesters) D (third trimester)	Minimal Possible risk of gastroschisis	Decreased fetal renal blood flow causing oligohydramnios Closure of the ductus arteriosus Prolongation of labor	Ibuprofen preferred for short half-life and limited transfer into breast milk
Prednisone	C	Possible increased risk of cleft palate with doses >20 mg daily	Maternal hyperglycemia leading to macrosomia	
Hydroxychloroquine	C	Low risk of ocular toxicity	Decreases SLE flare; may decrease risk for cardiac neonatal SLE	AAP: compatible with lactation
Sulfasalazine	B	Minimal risk	Infant may have minimal immunosuppression	Compatible with lactation; theoretic risk for kernicterus: limit exposure for premature infants or those with jaundice
Methotrexate	X	5%-10% risk of anomaly with first-trimester exposure	Increased risk of pregnancy loss; treat with increased folic acid	Not advised
Leflunomide	X	High risk in animal studies; no known increased risk in human study	Cholestyramine	Not advised
Azathioprine	D	Minimal risk	Infant may be immunosuppressed at delivery	Not advised
Mycophenolate mofetil	D	Increased risk of anomalies, particularly in the ear	Increased miscarriage risk	Not advised
Cyclophosphamide	D	Increased risk with first-trimester exposure but not second or third trimester	Increased miscarriage risk	Not advised
TNF inhibitors	B	May not be increased; proposed associated with VACTERL association		May be allowable due to minimal transfer into breast milk and low absorption of immunoglobulins via the GI tract
Rituximab	C	No known risks of fetal malformations	Exposure just before conception or during pregnancy may lead to neonatal cytopenias	Unknown
Tocilizumab	C	Unknown	May increase miscarriage risk	Unknown

AAP, American Academy of Pediatrics; FDA, U.S. Food and Drug Administration; GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs; SLE, systemic lupus erythematosus; TNF, tumor necrosis factor; VACTERL, Vertebral abnormalities, Anal atresia, Cardiac abnormalities, Tracheoesophageal fistula and/or Esophageal atresia, Renal agenesis and dysplasia, and Limb.

are pertinent in a pregnant woman because pregnancy requires tight blood pressure control and may induce insulin resistance (and often frank gestational diabetes), as well as osteopenia or osteoporosis of pregnancy. These issues can be exacerbated by steroids, so proper monitoring and calcium and vitamin D supplementation should be employed.

Nonfluorinated corticosteroids do not appear to put a fetus at risk for congenital abnormalities. The exception is a few reports of an increased risk of cleft lip and/or palate, a first-trimester risk. A meta-analysis looking at birth defects after maternal exposure to corticosteroids reported a 3.3 increase in the odds ratio of clefts after first-trimester exposure.⁹⁶ Subsequent studies have been mixed, some showing similar results and some showing no difference. However,

should the findings be true, it should be noted that cleft palates occur at a rate of about 1/1000 in the general population and thus the risk with steroid use would increase this to 3/1000. This small increase in risk should be weighed against the need to treat active disease in the mother. There have also been rare isolated reports of neonatal cataracts and adrenal suppression in infants after corticosteroid use, which may be dose dependent.⁹⁰

The pharmacokinetics of prednisolone, the active form of prednisone, has been studied in breast milk.⁹⁷ Levels measured in the milk are typically less than 0.1% of the total prednisolone dose ingested by the mother, which when small to moderate doses are being used, is less than 10% of the infant's endogenous cortisol production. Ost and colleagues⁹⁷ evaluated a patient taking up to 80 mg of daily

prednisolone and calculated that the prednisolone ingested from the milk would add, at most, 10% to the endogenous corticosteroid production of the infant, which may have little clinical significance. Peak steroid levels in breast milk occur about 2 hours after a dose is taken and rapidly decline.⁹⁸ These small to moderate amounts of corticosteroids do not appear to have adverse effects on the developing infant; however, exposure may be minimized if nursing is done 3 to 4 hours after the dose is taken.

Hydroxychloroquine

HCQ crosses the placenta, and infants may be born with similar serum concentrations of the drug as the mother. The literature includes several reports of isolated women taking daily chloroquine during multiple pregnancies and having infants born with anomalies, most commonly ocular. This finding, however, has not been replicated in studies of HCQ. Researchers systematically evaluated almost 100 infants in several studies for ocular toxicity and did not find abnormalities.⁹⁹⁻¹⁰³ A recent study of 21 infants with in utero HCQ exposure found electroretinogram abnormalities in 6, with resolution in one after 7 months. Prior reports of six children and four children with in utero HCQ exposure did not find abnormalities with this testing.^{104,105} Further information about the lasting impact of HCQ on the retina of infants will be helpful. A study of cardiac conduction in exposed infants found no anomalies.¹⁰⁶ Several larger studies have found no increase in fetal anomalies in infants exposed to daily dosing of HCQ for rheumatologic disease.^{106,107}

The discontinuation of HCQ early in pregnancy is associated with SLE flare and decreased gestational age.^{106,107} An increase or decrease in preterm birth and pregnancy loss has not been statistically associated with HCQ use. A case-control study of cardiac neonatal lupus has found a protective effect from HCQ. Although univariate analysis in this study found a 70% decrease in cardiac neonatal lupus with HCQ use, multivariate analysis did not maintain statistical significance for this finding.¹⁰⁸ Prospective studies of HCQ for prevention of neonatal lupus would provide valuable clinical information for women with Ro/SSA antibodies.

HCQ does cross into breast milk but in limited quantities.^{109,110} Analysis of two lactating women taking HCQ estimated that a fully breast-fed infant would ingest an estimated 0.2 mg/kg/day of HCQ, compared with maternal dosing of 6 mg/kg/day.¹⁰⁴ The American Academy of Pediatrics has designated HCQ as compatible with breastfeeding with only minimal risk to the infant.¹¹¹ For this reason, breast-feeding is generally allowed in women taking HCQ.

Sulfasalazine

Fertility in women does not appear to be affected by SSZ use; however, it can lead to reduced fertility in men due to oligospermia and reduced sperm motility. Fortunately, this is not an irreversible event; normal spermatogenesis should return approximately 2 months after cessation of the drug. Men who want to conceive a child with a partner should be counseled to discontinue the medication 3 months prior.¹¹² It is also important to counsel men that, although fertility may be reduced, the use of SSZ is not

considered an effective form of contraception. Abnormal or reduced spermatogenesis is due to the SSZ metabolite sulfapyridine.

In contrast to its effects on men, SSZ is among the more preferred DMARDs for pregnant women who require ongoing disease-modifying therapy. Much of the data regarding pregnancy outcomes with SSZ exposure is derived from the inflammatory bowel disease (IBD) literature. A recent meta-analysis of 2200 pregnant women with IBD (642 received SSZ or related agents) found no statistically significant differences for congenital anomalies (OR, 1.16; 95% confidence interval [CI], 0.76 to 1.77) or other adverse pregnancy outcomes.¹¹³ These data confirm several other reports of population-based studies published over the past several decades.^{114,115} Congenital abnormalities discussed in isolated case reports have not been seen in systematic population-based studies.

Two additional considerations are worth noting. The first is the theoretic risk that SSZ may cause folate deficiency as it inhibits dihydrofolate reductase and the cellular uptake of folate.¹¹⁶ Pregnant women require at least 800 µg of folic acid replacement, which should be continued, and perhaps increased, during SSZ use. Folic acid deficiency has been linked to neural tube defects, which can occur as early as 5 weeks of pregnancy (just 3 weeks after conception), so this should be part of the preconception planning discussions. The second consideration is in regards to late-term use. A SSZ metabolite called sulfapyridine can cross the placenta, displace bilirubin from albumin, and possibly lead to neonatal jaundice.¹¹⁷ Although there are no reports of this occurring after in utero exposure to SSZ, one may consider holding SSZ use during lactation in a preterm or jaundiced baby for 1 to 2 months.

Except in the setting of prematurity, hyperbilirubinemia, or other acute stresses, SSZ is considered safe during lactation. Sulfapyridine levels in breast milk were found to be about 30% to 60% of those in the mother's serum,¹¹⁸ but should not pose risk for a healthy full-term infant.

Azathioprine

Azathioprine (AZA) carries an FDA classification of D, but it is widely viewed as one of the safest immunosuppressants available in pregnancy. While animal studies have identified congenital anomalies after in utero exposure, several large human studies in women taking the drug for SLE, inflammatory bowel disease, or solid-organ transplants have documented no risk of congenital anomalies following exposure. The few reported congenital anomalies in pregnancies exposed to AZA seem to be sporadic without a specific organ or pathogenic pattern. Pregnancies exposed to AZA, however, are at increased risk for preterm birth and growth retardation. Whether this is more related to the drug or the underlying maternal disease remains unclear.

AZA does cross the placenta, and infants are born with low levels of the drug and its metabolites. This leads to a theoretic risk for neonatal infection that has not been borne out in prospective studies.

For some women with systemic rheumatologic disease, the benefits of disease suppression outweigh the potential risks of AZA. Significant SLE activity, for example, is associated with up to a 40% risk of miscarriage and over a 60%

risk for preterm birth. Any potential harm from AZA use in pregnancy is dwarfed by these statistics. Two small studies of AZA use in SLE pregnancies show an association between AZA therapy and pregnancy loss that is strongly confounded by SLE activity.^{119,120} For SLE pregnancies in which SLE activity remains quiescent with AZA therapy, there is no increase in pregnancy loss or preterm birth.¹¹⁹

Although AZA does not appear to transfer into breast milk to a significant degree, breast-feeding while taking this medication is discouraged by the World Health Organization Working Group on Drugs and Human Lactation.¹²¹

Methotrexate (FDA Class X)

Methotrexate is a dihydrofolate reductase inhibitor that impairs purine metabolism, leading to abnormalities in ribonucleic acid and deoxyribonucleic acid synthesis. It is a known teratogen that can cause dysmorphic facial features, skull and limb abnormalities, and growth deficiency. In addition, developmental delay and mental retardation have been reported.¹²² The main toxicity appears to occur before 8 weeks' gestation and can occur with high-dose methotrexate for cancer therapy or pregnancy termination, and in low-dose methotrexate it is used to treat rheumatologic disease. Although case reports include descriptions of significant anomalies, prospective and retrospective cohorts of pregnancies exposed to this drug do not demonstrate a high rate of anomalies. A collection of 97 pregnancies in women with rheumatologic disease exposed to methotrexate from 6 reports found a rate of anomaly of 7% of live births. Elective termination was frequent (17%), and spontaneous miscarriage was high (23% of pregnancies not terminated).¹²²

All women taking methotrexate should be well informed about the risk for fetal anomalies and pregnancy loss associated with the drug. A reminder that methotrexate is routinely used to terminate ectopic pregnancies (at a dose about threefold the rheumatologic dose) can make this risk clearer. If a pregnancy is exposed to methotrexate, an increased dose of folic acid may be initiated; folinic acid therapy has been demonstrated to decrease the risk for fetal anomalies in some animal models.¹²² For women who have discontinued methotrexate at least 3 months before conception, as is recommended, continuation of folic acid through pregnancy is recommended.

Given the relatively low rate of fetal anomalies identified in pregnancy cohorts, routine recommendation for pregnancy termination is not required but should be offered to all women. Women who decide to continue pregnancy must understand the risks for both pregnancy loss and fetal abnormalities. In wanted pregnancies, ultrasound screening for fetal anomalies should be encouraged with consideration of termination if these are identified. Unfortunately, ultrasound may not be able to uncover all fetal anomalies, leaving some risk for anomaly despite normal evaluations.

Methotrexate has not been studied in lactation and is not recommended.

Leflunomide

It is known that leflunomide causes fetal anomalies in animals, primarily CNS and skeletal anomalies. When leflunomide was given to rats at only 1% of the human dose, it

resulted in fetal anomalies, decreased birth weight, and increased mortality in the offspring after birth.²² On the basis of available animal data, the FDA has categorized leflunomide as category X; this indicates that clear associations between the drug and fetal abnormalities have been identified and the risks of use in pregnant humans outweigh any potential benefits. In his article reviewing reproductive risks of leflunomide, Brent nicely outlines managing elimination of leflunomide in a woman who has become pregnant on leflunomide or desires pregnancy largely on the basis of manufacturer and FDA recommendations.¹²³ The level believed to be safe in humans is 0.02 mg/L (i.e., ≈ 10 half-lives). If a woman treated with leflunomide wants to become pregnant, the medication should be stopped and cholestyramine administered to decrease the blood levels rapidly to this level. Cholestyramine, 8 g three times daily, reduces the half-life of the active metabolite from what has been found in early pharmacokinetics analysis to be up to 96 days to approximately 1 day. Therefore, a 10- to 11-day regimen of cholestyramine, 8 g three times daily, is recommended. This approach is certainly conservative but was suggested by the FDA and is the manufacturer's recommendation. Plasma levels of the drug should be verified to be less than 0.02 mg/L by two separate tests performed 2 weeks apart. If levels still remain greater than 0.02 mg/L, then the regimen should continue to be administered and women should use effective contraception until levels are less than 0.02 mg/L. Based on the natural half-life of the drug (again, ≤ 96 days) it may take up to 2 years to reach plasma active metabolite levels of 0.02 mg/mL due to individual variations; therefore levels should be checked (and if necessary cholestyramine administered) in any patient who has been treated with leflunomide in the previous 2 years. This practice is also supported by a panel of 29 experts who participated in a consensus workshop on antirheumatic drugs during pregnancy and lactation.⁹⁰

Despite the dramatic fetal anomalies seen in rodents after leflunomide exposure, the available human data are more reassuring. Data from the OTIS Collaborative Research Group prospectively evaluated 64 women with RA treated with leflunomide (95% of which were treated with cholestyramine early in the pregnancy), 108 women with RA not treated with leflunomide, and 78 healthy pregnant women. The rate of major structural defects in the exposed group was 5.4%, which was insignificant compared with both comparison groups (4.2% and 4.2%, respectively, $P = .13$). Although a small study group, these results are encouraging and suggest that these defects may be preventable with appropriate and early intervention.⁴³ It is unknown how leflunomide exposure may affect a young infant, and lactation is considered to be unsafe until more data become available.

Mycophenolate Mofetil

MMF, a reversible inhibitor of inosine monophosphate, was FDA approved in 1995 for use in solid organ transplantation. It is used with increasing frequency for the treatment of autoimmune conditions including lupus nephritis. MMF has been shown to be teratogenic in experimental animals, and increasing data through case reports and registry studies support its teratogenicity in humans.¹²⁴⁻¹²⁷ MMF readily

crosses the placenta. Exposure to MMF during embryogenesis leads to a possible increased rate of spontaneous abortions¹²⁶ and an estimated 22% to 26% rate of congenital malformations.^{125,126} A distinctive MMF embryopathy has been identified as the “EMFO tetrad: Ear (microtia and auditory canal atresia); Mouth (cleft lip and palate); Fingers (brachydactyly of fifth fingers and hypoplastic toenails; and Organs (cardiac, renal, CNS, diaphragmatic, and ocular).”¹²⁵ Based on these data, the FDA has recently included a black box warning on the package insert discussing teratogenicity as a concern with use of MMF in women of childbearing potential.¹²⁸ Use of reliable contraception is mandatory for women of childbearing potential. Women taking MMF who want to become pregnant should discontinue the drug at a minimum of 6 weeks before conception. In cases in which ongoing immunosuppression is required to maintain the mother’s health, azathioprine is often considered a safer alternative. There are no data on the excretion of MMF into breast milk or the effect if ingested by infants. Therefore lactation is also contraindicated while using MMF.

Cyclophosphamide

Cyclophosphamide (CYC) is an alkylating agent that alters DNA synthesis. It has an FDA pregnancy classification of D, indicating a significant and known risk with fetal exposure. First-trimester exposure to CYC carries a high risk for major congenital anomalies, particularly of the palate, limbs, and eyes, as well as miscarriage. The rate of these anomalies is unknown due to difficulties with prospective studies, but these malformations are not found in all live births after first-trimester exposure.

In the second and third trimesters, the risks for congenital anomalies is far lower. While data is limited, pregnancies exposed because of maternal breast cancer in pregnancy have resulted in healthy, full-term infants. Among SLE pregnancies reported in the literature with mid to late trimester CYC exposure, two resulted in a fetal death and one in a successful preterm birth.¹²⁹⁻¹³¹ In these cases, the mother was very ill preceding the CYC dosing, making it likely that the pregnancy loss would have occurred without the CYC treatment, as well. When a pregnant woman has a life-threatening flare of rheumatologic disease in the latter half of pregnancy, treatment with CYC can be entertained. The significant risk of pregnancy loss in this situation, with or without CYC therapy, should be discussed with the woman prior to dosing.

CYC transfers into breast milk and has been associated with cytopenias in nursing infants.¹³¹ For this reason, women taking CYC should not breast-feed.

Tumor Necrosis Factor

Due to a lack of fetal anomalies or adverse pregnancy outcomes found in animals exposed to TNF inhibitors, these all carry an FDA pregnancy classification of B. This does not mean, however, that they have been satisfactorily confirmed as safe in human pregnancy. Limited prospective data on pregnancies exposed to TNF inhibitors suggest that there is not an increase in fetal anomalies, pregnancy loss, or preterm birth.⁴⁶

One report of the FDA drug toxicity database hypothesizes that in utero TNF inhibitor exposure is associated with Vertebral abnormalities, Anal atresia, Cardiac abnormalities, Tracheoesophageal fistula and/or Esophageal atresia, Renal agenesis and dysplasia, and Limb (VACTERL) association.¹³² VACTERL association is diagnosed when an infant is born with at least three major anomalies that are included in the previous definition. This hypothesis was prompted by the diagnosis of this association in an infant exposed to etanercept 50 mg twice a week throughout gestation for maternal PsA. In the FDA database, another 54 anomalies in 40 infants were identified. None of these infants met criteria for VACTERL association, but 56% of these anomalies fell into the categories included in the VACTERL diagnosis. Although this report brings to light potentially important data, it has several drawbacks when applied to clinical practice. Most importantly, the total number of pregnancies exposed to TNF inhibitors is unknown. In order to find an anomaly rate typical in the general population (3%), only 1200 pregnancies would require exposure to produce 40 infants with anomalies. In addition, the most common anomalies reported in the FDA database including cardiac and urogenital anomalies are also the most common seen in the general population. The more uncommon anomalies are only reported in one to two infants after TNF inhibitor exposure, leading to difficulty associating these with a specific cause.

Although immunoglobulins do not cross the placenta in the first half of pregnancy, the rate of immunoglobulin transfer increases linearly through the following weeks, leading to a large transfer in the weeks before term. At birth, the infant has a higher concentration of maternal antibodies than the mother.¹³⁴ Based on this finding, it is hypothesized that TNF inhibitors do not cross the placenta before 16 weeks’ gestation but do cross in increasing concentrations as the pregnancy progresses. Infliximab has been documented to cross the placenta in high levels close to term with infants exposed in utero having serum levels similar to the mother at delivery.¹³⁵ The infant serum levels slowly decrease over the following weeks to months. Etanercept, on the other hand, may cross at lower levels. A single infant born after etanercept throughout pregnancy had a serum concentration under 4% of the maternal serum concentration¹³⁶ (Figure 39-3).

IgG immunoglobulins do not transfer into human breast milk, and they are not absorbed by the human infant gastrointestinal tract. Six women taking infliximab during lactation have been documented to have no drug in their breast milk. Two women taking etanercept have been documented to have minimal drug in their breast milk. Infants fully breast-fed by mothers taking both of these drugs have not had increasing serum TNF inhibitor concentrations.⁴⁵

Rituximab

Rituximab is a chimeric (mouse/human) monoclonal antibody directed against B cell surface antigen CD20 that is indicated for the treatment of B cell lymphoma and moderate to severe RA. In addition, it has been studied and is occasionally used off label for the treatment of other autoimmune diseases and hematologic disorders (SLE, multiple sclerosis, autoimmune cytopenias, thrombotic

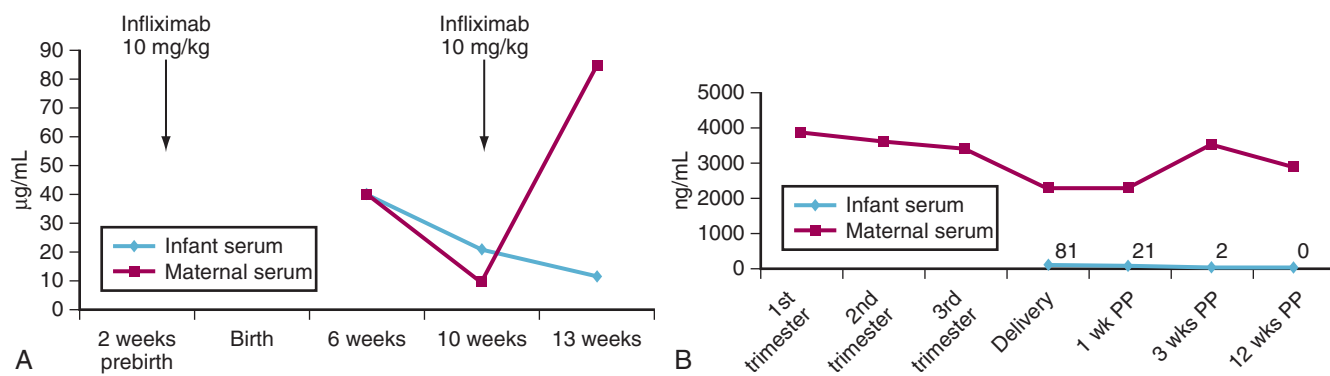

Figure 39-3 In utero tumor necrosis factor inhibitor exposure leads to transfer of the drug to the infant. **A**, Infliximab 10 mg/kg was administered for severe Crohn's disease five times in pregnancy with the last dose given 2 weeks before delivery. At 6 and 10 weeks' postpartum (PP), the maternal and infant serum concentrations of infliximab were similar. Following a postpartum maternal dose of infliximab, the infant continued to have decreasing serum levels despite breast-feeding. **B**, Etanercept (25 mg subcutaneously twice a week) was administered throughout pregnancy and lactation to a woman with severe rheumatoid arthritis. At delivery, the infant had a serum level 3.5% of the maternal level. The infant level decreased over the following weeks despite breast-feeding.¹³⁶

thrombocytopenic purpura). Administration results in rapid and sustained depletion of peripherally circulating CD20⁺ B cells. Like other monoclonal antibodies, rituximab has an IgG construct and therefore crosses the placenta. Little IgG is seen in fetal circulation during the first trimester of pregnancy. Levels slowly rise during the second trimester and reach maternal serum concentrations by approximately 26 weeks' gestation. Maximum IgG transfer across the maternal-fetal interface occurs during the last 4 weeks of gestation, and fetal concentration often exceeds maternal concentration at term delivery. Rituximab carries an FDA pregnancy classification of C. Several case reports of rituximab administered during the second or third trimester of pregnancy for acute life-threatening maternal disease have been published. They have not found associations between antenatal rituximab exposure and adverse pregnancy outcomes or congenital malformations. More recently a study describing pregnancy outcomes following preconceptional or antenatal exposure to rituximab in the rituximab global safety database was published.^{137,138} Of 153 pregnancies with known outcomes, 90 resulted in live births. Twenty-two infants were born prematurely; with one neonatal death of unknown cause at 6 weeks. Eleven neonates had hematologic abnormalities, none with corresponding infections. Four neonatal infections were reported (fever, bronchiolitis, CMV hepatitis, and chorioamnionitis); the rate of congenital malformations was not different than the 3% to 4% expected in the general population. Two congenital malformations were identified: clubfoot in one twin and cardiac malformation in a singleton birth. In almost all cases, pregnancy was complicated by active maternal disease and concomitant use of potentially teratogenic medications (including combined chemotherapy with alkylating agents, methotrexate, MMF, and warfarin). The authors concluded that there was no apparent pattern of adverse outcomes (perinatal infections, symptomatic cytopenias, or congenital malformations) associated with rituximab exposure; however, patients should be followed closely if a pregnancy occurs within 6 months following rituximab administration or therapy is indicated to treat severe maternal disease during an established pregnancy. No data are available regarding the

concentration of rituximab in breast milk or its effects on breast-feeding infants.

Tocilizumab

The IL-6 inhibitor tocilizumab is an IgG antibody, so it likely crosses the placenta in the latter half of pregnancy. A preliminary report of pregnancy toxicity included 33 pregnancies, largely to women enrolled in the drug studies performed for FDA approval of this drug. Of these, 48% were electively terminated and 9% had unknown outcomes. Of the remaining 16 pregnancies, 5 (31%) resulted in a spontaneous abortion, 8 (50%) resulted in a full-term infant, 1 resulted in an infant death due to lung disease, and 1 was a gestational trophoblastic tumor.¹³⁹ This suggests a higher rate of miscarriage than would be expected in RA pregnancies, but an assessment of further risks is not possible. No lactation information about this drug is available, so at this time it is not recommended.

History and Physical Examination of the Musculoskeletal System

JOHN M. DAVIS III • KEVIN G. MODER •
GENE G. HUNDER

KEY POINTS

Taking a detailed and accurate history is crucial for making the correct diagnosis for patients with musculoskeletal diseases.

The cardinal symptoms of musculoskeletal disease are pain, stiffness, swelling, limitation of motion, weakness, fatigue, and loss of function.

Understanding the anatomy, the planes of motion, and particularly the configuration of the synovial lining is imperative for proper physical diagnosis of musculoskeletal diseases.

It is important to record qualitative and quantitative aspects of the joint examination to monitor disease activity in patients with inflammatory arthropathies.

Early recognition of how patients' psychosocial factors affect their musculoskeletal symptoms and musculoskeletal examination enhances clinical assessment.

HISTORY IN A PATIENT WITH MUSCULOSKELETAL DISEASE

Taking an accurate and comprehensive history of a patient's musculoskeletal symptoms is crucial for making the correct diagnosis. This history must include a precise understanding of what the patient means by the description of symptoms. The physician must obtain a detailed account of symptom onset, location, patterns of progression, and severity, as well as exacerbating and alleviating factors and associated symptoms. The relationship of the symptoms to psychosocial stressors is important and should be determined. The impact of the symptoms on all aspects of the patient's functioning must be assessed to guide therapy.

The effects of current or previous therapy on the course of the illness are helpful in efforts to understand current symptoms. Response to anti-inflammatory or glucocorticoid medications may suggest an inflammatory origin. Such responses are not specific to inflammatory rheumatic diseases, however, and must be considered in light of the entire

history and physical examination. The physician must assess compliance with therapies for musculoskeletal diseases. Noncompliance with the recommended treatment must be differentiated from treatment failure as the explanation for the patient's lack of improvement.

While the physician is taking the patient's history, the patient provides verbal and nonverbal clues to the nature of the illness and how the patient has responded to it. Patients with early rheumatoid arthritis may hold their hands in a flexed posture to minimize intra-articular pressure and pain. Some patients may be overly concerned, whereas others may seem inappropriately indifferent to their symptoms. The physician must appreciate the patient's understanding of the illness and attitudes toward it to begin effective treatment.

Pain

Pain is the most common symptom that brings a patient with musculoskeletal diseases to the physician. Pain is a subjective hurting sensation or experience described in various terms, often of actual or perceived physical damage. Pain is a complex sensation that is difficult to define, qualify, and measure. The patient's pain may be modified by emotional factors and previous experiences.

The character of the pain usually is best defined early in the interview because this can be helpful in categorizing the patient's complaints. Aching in a joint area suggests an arthritic disorder, whereas "burning" or "numbness" in an extremity may indicate a neuropathy. Descriptions of pain as "excruciating" or "intolerable" when the patient is otherwise able to function provide a clue that emotional or psychosocial factors are contributing to or amplifying the symptoms.

The physician must elicit the distribution of the patient's pain and determine whether this fits with anatomic

structures. Patients describe their pain location in terms of body part names, but frequently the terms are used in a nonanatomic manner. Patients frequently complain of “hip” pain when actually referring to pain in the low back, buttock, or thigh. The interviewer must attempt to clarify this complaint by asking the patient to point to the area of pain with one finger. Pain localized in the distribution of a joint or joints likely reflects an articular disorder. Pain may localize to bursae, tendons, ligaments, or nerves, implying disorders of these structures. In contrast to superficial structures, deep structures often give rise to poorly localizing pain. Similarly, pain arising from small, peripheral joints is often more focal than pain arising from proximal, large joints, such as the shoulders and hips. Pain that is widespread, vaguely described, and not respecting anatomic distributions generally suggests a chronic pain syndrome, such as fibromyalgia or psychiatric disease.

The severity of pain should be assessed. A common approach is to ask the patient to describe the level of pain on a numeric scale of intensity from 0 (no pain) to 10 (very severe pain). For monitoring of disease activity of inflammatory arthritis, measuring pain on a visual analogue scale by having the patient mark the severity of pain over the past week on a 100-mm line can be helpful. Similar scales are used in validated instruments such as the McGill Pain Questionnaire.

The physician must determine what exacerbates and alleviates the pain. Joint pain present at rest but worse with movement suggests an inflammatory process, whereas pain occurring primarily with activity and relieved by rest generally indicates a mechanical disorder, such as degenerative arthritis. Timing of pain symptoms during the day and night also provides important information, as discussed in the next section.

Stiffness

Stiffness is a common complaint among patients with arthritis. What is meant by stiffness varies from patient to patient, however. Some patients may use the term *stiffness* to refer to pain, soreness, weakness, fatigue, or limitation of motion.¹ Rheumatologists generally use the term *stiffness* to describe discomfort and limitation on attempted movement of joints after a period of inactivity. This “gel” phenomenon occurs usually after an hour or more of inactivity. The duration of stiffness related to inactivity varies, with mild stiffness lasting minutes and severe stiffness lasting hours.

Morning stiffness is an early feature of inflammatory arthropathies and is particularly noted in rheumatoid arthritis and polymyalgia rheumatica, in which morning stiffness may last for several hours. The absence of morning stiffness does not exclude inflammatory arthritis, but its absence is uncommon. A useful question to assess morning stiffness is this: “In the morning, how long does it take for your joints to limber up to as good as they are going to get for the day?” Morning stiffness associated with noninflammatory joint diseases, such as degenerative arthritis, generally is of short duration (usually <30 minutes) and is less severe than stiffness of inflammatory joint disease. Additionally, the degree of stiffness in noninflammatory joint diseases is related to the extent of use of the damaged joint—stiffness is worse after excessive use, generally improving within several days

to the baseline level. Morning stiffness is not specific for inflammatory arthropathies and may be described by patients with fibromyalgia or chronic idiopathic pain syndromes, neurologic disorders such as Parkinson’s disease (although generally without limbering up), and sleep-related breathing disorders.

Limitation of Motion

Limitation of motion is a common complaint among patients with articular disorders. This complaint must be differentiated from stiffness, which usually is transient and variable, whereas limitation of motion secondary to joint disease is generally fixed and varies less over time. The interviewer should determine the extent of disability resulting from the restriction in joint motion. The duration of the restriction in joint motion frequently predicts the likelihood of improvement with interventions such as oral and intra-articular glucocorticoids or physical therapy. Determining the rapidity of onset of the limitation of motion may be helpful in the differential diagnosis; abrupt onset of the limitation of motion suggests a structural derangement, such as a tendon rupture or torn knee cartilage, whereas insidious onset of restricted joint motion is more common with inflammatory joint disease.

Swelling

Joint swelling is an important symptom in patients with rheumatic diseases. The presence of true joint swelling narrows the differential diagnosis in a patient with arthralgia. To determine whether the swelling is related to joint synovitis as opposed to soft tissue conditions, clarifying the anatomic location and distribution of the swelling is key. Diffuse soft tissue swelling can occur because of venous or lymphatic obstruction, soft tissue injury, or obesity. The description of swelling in patients with such conditions usually is ill defined or is not in a distribution of particular joints, bursae, or tendons. Obese patients may interpret normal adipose tissue over the medial aspect of the elbow, the knee, or the lateral aspect of the ankle as joint swelling. In contrast, patients with inflammatory arthritis may describe swelling of joints in a distribution typical of a specific disease—symmetric swelling of the metacarpophalangeal joints and wrists in rheumatoid arthritis, or swelling of several toes and a knee in psoriatic arthritis.

It is useful to delineate the onset and progression of swelling and the factors that influence it. Swelling of a joint resulting from synovitis or bursitis frequently is associated with discomfort with motion because of tension on the inflamed tissues. If swollen tissues are periarticular, however, no discomfort may be present with joint motion because the inflamed tissues are not stressed. Swelling of a confined structure, such as a synovial cavity or bursa, is most painful when it has developed acutely, whereas a similar degree of swelling that has developed slowly often is much more tolerable.

Weakness

Weakness is another common complaint that can be associated with myriad different subjective meanings. True

weakness is the loss of muscle power. When present, it is demonstrable on physical examination.

The temporal course of weakness is important to the differential diagnosis. Weakness of sudden onset without trauma often indicates a neurologic disorder, such as an acute cerebrovascular event, which generally results in a fixed, nonprogressive deficit. Weakness of insidious onset more often suggests a muscle disease, such as an inflammatory myopathy (i.e., polymyositis). The latter tends to be ongoing and progressive. Weakness that is intermittent suggests a disorder of the neuromuscular junction, such as myasthenia gravis. Patients with this disease may describe muscle fatigue with activity as opposed to true weakness.

The physician should determine the distribution of the patient's weakness. Proximal weakness that is bilateral and symmetric suggests an inflammatory myopathy. In contrast, inclusion body myositis causes an asymmetric and more distal weakness. The presence of a unilateral or isolated deficit generally indicates a neurogenic origin. Distal weakness, in the absence of joint findings, generally indicates neurologic disorders, such as peripheral neuropathy. Patients with peripheral neuropathies also complain of pain and sensory symptoms, such as paresthesias. In contrast, patients with inflammatory myopathy often present with painless weakness.

Inquiring about the patient's family history may provide valuable information. A history of other family members with similar symptoms may increase the likelihood that the patient has a hereditary disorder, such as muscular dystrophy or familial neuropathy.

It also is important to review medication taken recently or currently. Many medications, including corticosteroids and lipid-lowering agents, can cause muscle injury. Less commonly, environmental exposure can lead to symptoms of weakness. Heavy metal poisoning causes a peripheral neuropathy. Dietary exposure also should be investigated such as eating undercooked pork as a source of trichinosis. Excessive alcohol intake has been associated with neuropathy and myopathy.

Taking a complete review of systems is helpful in evaluating a patient with weakness. Constitutional symptoms, such as weight loss and night sweats, may indicate the presence of a malignancy as the cause of generalized weakness. Rash, arthralgia, or Raynaud's phenomenon may prompt further testing for a connective tissue disease.

Fatigue

Patients with musculoskeletal disorders frequently complain of fatigue. *Fatigue* can be defined as an inclination to rest even though pain and weakness are not limiting factors. Fatigue after varying degrees of activity that is relieved by rest is normal. Patients with rheumatic diseases experience fatigue even without activity. Fatigue generally improves as the systemic rheumatic disease improves. Malaise frequently occurs with, but is not synonymous with, fatigue. Malaise indicates the lack of well-being that often occurs at the onset of an illness. Fatigue and malaise may occur in the absence of identifiable disease, and psychosocial factors, anxiety, or depression may account for the symptoms.

Loss of Function

The comprehensive history should include an assessment of the patient's ability to perform activities of daily living, as loss of function is a common manifestation of musculoskeletal disease with serious impact on health and quality of life. The extent of disability may vary from loss of the ability to use one finger joint due to arthritis to complete physical incapacitation due to severe inflammatory polyarthritis. Irrespective of the cause, loss of physical function often has a profound impact on patient social activities, exercise routine, work capacity, and even basic self-care. Assessing for the presence and degree of functional disability is important in evaluating the severity of illness and in making treatment recommendations, particularly in rheumatoid arthritis, where disability is among the best predictors of long-term outcomes and mortality.^{2,4}

Functional capacity is assessed first by asking general questions about the patient's ability to perform daily activities, including grooming, dressing, bathing, eating, walking, climbing stairs, opening doors, carrying objects, and so forth. A report of a specific loss of function, such as difficulty opening a milk carton, should be investigated further to clarify why the task is difficult, which will inform the differential diagnosis and guide clinical examination. This information will also yield important information for management, such as opportunities for physical and occupational therapy, use of splints/braces, and so forth. Overall functional capacity may be evaluated with the use of an instrument such as the Health Assessment Questionnaire (see Chapter 33), which is widely used in research and in the clinic to monitor changes in physical function in response to therapy among patients with rheumatoid arthritis and other rheumatic diseases.

SYSTEMATIC METHOD OF EXAMINATION

The musculoskeletal examination should be a systematic, thorough assessment of the status of the joints, periarticular soft tissues, tendons, ligaments, bursae, and muscles. Rheumatologists commonly begin by examining the upper extremities followed by the trunk and lower extremities, but many routines may be effective, provided that a systematic, consistent approach is used. Gentle handling of tender and painful joints enhances cooperation by the patient and allows an accurate evaluation of the joints.

The general aim of the examination of the joints is to detect abnormalities in structure and function. Key signs of articular disease include swelling, tenderness, limitation of motion, crepitation, deformity, and instability.

General Observation

A general examination of the patient should be done to look for any signs of systemic illness. This should include an examination of the skin, noting signs of pallor (which may suggest anemia), nodules (which may suggest rheumatoid arthritis or gout), or rashes (which may suggest lupus, vasculitis, or dermatomyositis). The patient should be

appropriately undressed for examination. The physician should assess gait by asking the patient to walk in the examining room or down the hallway, because an antalgic gait may be seen in various musculoskeletal disorders of the spine or lower extremities, and various gait disorders may occur in neuromuscular diseases. The ability of the patient to arise and transfer to the examining table should also be evaluated, as this will provide information on pain, proximal muscle strength, and overall physical function. The patient should be assessed for appearance of the muscles, including bulk, tone, and tenderness. Muscle bulk should be compared on one side of the body with the other to look for any asymmetry, hypertrophy, or atrophy. The patient's manner and body language may provide information on his or her mood and anxiety level, which merits consideration in evaluating pain and tenderness.

Swelling

Swelling around a joint may be caused by intra-articular effusion, synovial proliferation, periarticular subcutaneous tissue inflammation, bursitis, tendinitis, bony enlargement, or extra-articular fat pads. A keen understanding of the anatomic configuration of each joint's synovial membrane is crucial in differentiating soft tissue swelling secondary to a joint effusion from swelling of periarticular tissues. First, the examiner should inspect the joints for visible evidence of swelling, such as loss of normal landmarks or contours. It is frequently helpful to visually compare the same joints on both sides of the body to detect subtle evidence of swelling and to appreciate symmetry.

Second, the examiner should palpate each joint. The normal synovial membrane is too thin to palpate, whereas the thickened synovial membrane in many chronic inflammatory arthritides, such as rheumatoid arthritis, may have a “doughy” or “boggy” consistency. In some joints, such as the knee, the extent of the synovial cavity can be delineated on physical examination by compressing the fluid into one of the extreme synovial recesses. The edge of the resulting bulge may be palpated more easily. If this palpable edge is within the anatomic confines of the synovial membrane and disappears on release of compression, the distention usually represents synovial effusion; if it persists, it is an indication of a thickened synovial membrane. Reliable differentiation between synovial membrane thickening and effusion is not always possible by physical examination, however. Ultrasonography is being used increasingly as an extension of the physical examination, allowing the examiner to differentiate between synovial proliferation and effusion.

Tenderness

In the musculoskeletal examination, tenderness indicates unusual discomfort on palpating and putting pressure on articular and periarticular tissues. Localizing the tenderness to palpation may assist the examiner in determining whether the pathology is intra-articular or periarticular in location, such as a fat pad, tendon attachment, ligament, bursa, or muscle, or skin. It can be useful to palpate structures that are not involved to assess the importance of tenderness. Finding tender joints in a patient who also has numerous

other myofascial tender points is less of a concern for arthritis than finding tender joints in a patient with no extra-articular tenderness.

Limitation of Motion

Limitation of motion is a common manifestation of articular disease; the examiner must know the normal type and range of motion for each joint. Comparison of the affected joint with an unaffected joint of the opposite extremity is useful in evaluating individual variation. Restricted joint motion may be caused by changes in the joint itself or in periarticular structures. To distinguish these possibilities, it is crucial to compare the passive with the active range of motion. If the passive range of motion is greater than the active range of motion, the restriction may be the result of pain, weakness, or the state of articular or periarticular structures. It also is important to distinguish muscle tension from a true limitation of joint motion, emphasizing the importance of ensuring relaxation of the patient. Pain that occurs with attempts to move a joint passively to the limit of range of motion in one plane is referred to as *stress pain*. Pain in the joint with attempted active or passive range of motion usually indicates an abnormality in the joint.

Crepitation

Crepitation is a palpable or audible grating or crunching sensation produced by motion. This sensation may or may not be accompanied by discomfort. Crepitation occurs when roughened articular or extra-articular surfaces are rubbed together by active motion or by manual compression. Fine crepitation often is palpable over joints involved by chronic inflammatory arthritis and usually indicates roughening of the opposing cartilage surfaces as a result of erosion or the presence of granulation tissue. Coarse crepitation may be caused by inflammatory or noninflammatory arthritis. Bone-on-bone crepitus produces a higher-frequency, palpable, audible squeak. Crepitation from within a joint should be differentiated from cracking or popping sounds caused by the slipping of ligaments or tendons over bony surfaces during motion. The latter phenomena are usually less contributory to the diagnosis of joint disease and may be heard over normal joints. In scleroderma, a distinct, coarse, creaking, leathery crepitation may be palpable or audible over tendon sheaths.

Deformity

Deformity of the joints may manifest as a bony enlargement, articular subluxation, contracture, or ankylosis in nonanatomic positions. Deformed joints usually do not function normally, frequently restrict activities, and may be associated with pain, especially with overuse. Occasionally, a deformed joint may function well but is a cosmetic concern. Joint deformities may be reversible or irreversible. Multiple swan neck deformities of the fingers that can be corrected with manipulation may indicate Jaccoud's arthropathy of lupus. In contrast, hand deformities in rheumatoid arthritis generally are not correctable.

Instability

Joint instability is present when the joint has greater than normal movement in any plane. *Subluxation* refers to a joint in which there is partial displacement of the articular surfaces but still some joint surface-to-surface contact. A dislocated joint has lost all cartilage surface-to-surface contact. Instability is best determined by supporting the joint between the examiner's hands and stressing the adjacent bones in directions in which the normal joint does not move. The patient must be relaxed during the examination because muscle tension may stabilize an otherwise unstable joint. A knee with a deficient ligament might appear stable if the patient contracts the quadriceps muscles during evaluation.

Other Aspects of the Examination

Examinations of the cervical spine and low back are discussed in Chapters 45 and 47.

RECORDING THE JOINT EXAMINATION

Documentation of the joint examination is important in making decisions about therapy, monitoring the activity of arthritis, and determining the efficacy of interventions. Many different recording methods have been described. Abbreviations for each joint can be used, such as PIP for the proximal interphalangeal joints. The S-T-L system has been used historically to record the degree of swelling (S), tenderness (T), and limitation of motion (L) of each joint on the basis of a quantitative estimate of gradation.⁵ This method remains useful but is used less commonly today because of increasing reliance on electronic medical records. It is easier to describe joint findings in narrative form, for example, "there is 2+ swelling of the second and third MCP joints," where grade 0 indicates no swelling, grade 1 indicates palpable synovial thickening, grade 2 indicates loss of normal joint contours, and grade 3 indicates frank cystic swelling of the metacarpophalangeal joint. An alternative method is to record joint examination findings using a schematic skeleton or homunculus. When accuracy is necessary, the range of motion of individual joints may be measured using a goniometer.

Joint counts are being used increasingly to monitor the activity of inflammatory arthritides in practice and in clinical trials.⁶ For monitoring disease activity of rheumatoid arthritis, a 28-joint count for tenderness and swelling has been recommended. To assess the tender joint count, the examiner documents which joints the patient indicates are painful on palpation with enough pressure to blanch the nail bed of the examiner's thumb and index fingers. To assess the swollen joint count, the examiner documents which joints have palpable soft tissue swelling or fluctuance, excluding joints affected only by deformity or bony hypertrophy. The 28-joint count⁷ includes the shoulders, elbows, wrists, first to fifth metacarpophalangeal joints, first to fifth proximal interphalangeal joints, and knees on both sides of the body. Compared with more extensive joint counts, the 28-joint count has the advantage of being quick and easy to perform; however, it is limited by the fact that the ankles and metatarsophalangeal joints are not included, so active

disease in the feet may be underestimated. The 28-joint count is used to calculate the Disease Activity Score 28 (DAS28),⁸ which is a validated instrument used to monitor disease activity.

The function of the joints in normal use is not captured by assessments of tenderness, swelling, or range of motion, so other examination techniques are necessary. Other tests are available that attempt to measure joint function by assessing the patient's ability to perform a coordinated task (e.g., shoulder arc of motion, measuring the 50-foot walk time). The results of such functional tests may vary, however. Biologic factors, such as circadian changes in joint size and grip strength among rheumatoid patients observed during a 24-hour interval, contribute to variability.

INTERPRETING THE JOINT EXAMINATION

The physician must understand the significance of specific joint findings, both their presence and absence, to make appropriate treatment decisions. As with any diagnostic assessment, the accuracy and reliability of the joint examination are important considerations. With regard to accuracy in detecting physical signs of inflammatory synovitis, numerous studies have shown that joint examination is far less sensitive in detecting synovitis or effusions than high-resolution ultrasonography or magnetic resonance imaging.⁹⁻¹¹ Although it prevails that swollen joints are more specific for active synovitis, recent clinical studies have suggested that joint tenderness has similar value in predicting the progression of radiographic joint damage as compared with swelling.¹² Demonstrable physical signs of arthritis may be particularly subtle for patients with early disease.¹³ Thus, the examiner must consider the physical findings in view of the complete history of joint symptoms to make an accurate diagnosis, assess prognosis, and prescribe management.

The joint examination is also affected by variability. For observations such as joint tenderness or grip strength, interobserver variability usually is greater than intraobserver variability. Considerable intraobserver variability may be noted in observations of the same patient, even over a short interval. Interobserver reliability, in general, is higher for joint-line tenderness than for swelling and is specifically related to the underlying disease, such as higher reliability of the examination for joint swelling in rheumatoid arthritis than in psoriatic arthritis.¹¹

EXAMINATION OF SPECIFIC JOINTS

Temporomandibular Joint

The temporomandibular joint is formed by the condyle of the mandible and the fossa of the temporal bone just anterior to the external auditory canal. It is difficult to visualize swelling of this joint. The examiner may palpate the joint by placing a finger just anterior to the external auditory canal and asking the patient to open and close the mouth and to move the mandible from side to side.¹⁴ The presence of synovial thickness or swelling of minimal or moderate

degree can be detected most easily if the synovitis is unilateral or asymmetric compared with the other side. To assess vertical movement of the temporomandibular joint, the examiner should ask the patient to open the mouth maximally and then measure the distance between the upper and lower incisor teeth, normally 3 to 6 cm. Lateral movement can be determined by using incisor teeth as landmarks. Audible or palpable crepitus or clicking may be present in patients with and without evidence of severe arthritis.

Many arthritides can affect the temporomandibular joints, including juvenile and adult rheumatoid arthritis. Children in whom these joints are affected may develop micrognathia, resulting from arrested bone growth of the mandible. Patients without inflammatory arthritis may develop arthralgias of the temporomandibular joint, consistent with the temporomandibular joint syndrome (see Chapter 51). This syndrome is thought by some investigators to result from bruxism and is likely to be a form of myofascial pain, similar to fibromyalgia.

Cricothyroid Joints

The paired cricothyroid joints are formed by the articulation of the base of the small pyramidal arytenoid cartilage and the upper posterolateral border of the cricoid cartilage. The vocal ligaments (true vocal cords) are attached to the arytenoid cartilages. The cricothyroid joints are diarthrodial joints that normally move medially and laterally and rotate during opening and closing of the vocal cords. Examination of these joints is done by direct or indirect laryngoscopy. Erythema, swelling, and lack of mobility during phonation may result from inflammation of the joints. The cricothyroid joints may be involved in rheumatoid arthritis, trauma, and infection. Involvement in rheumatoid arthritis is more common than is clinically apparent. Symptoms may include hoarseness or a sense of fullness or discomfort in the throat, which is worse on speaking or swallowing. Severe airway obstruction may rarely occur.

Sternoclavicular, Manubriosternal, and Sternocostal Joints

The medial ends of the clavicles articulate on each side of the sternum at its upper end to form the sternoclavicular joints. The articulations of the first ribs and the sternum (sternocostal joints) are immediately caudal. The articulation of the manubrium and the body of the sternum is at the level of attachment of the second costal cartilage to the sternum. The third through seventh sternocostal joints articulate distally along the lateral borders of the sternum. The sternoclavicular joints are the only articulations in this group that are always diarthrodial; the others are amphiarthroses or synchondroses. The sternoclavicular joints are the only true points of articulation of the shoulder girdle with the trunk. These joints are just beneath the skin; synovitis usually is visible and palpable. These joints have only slight movement, which cannot be accurately measured.

The sternoclavicular joints are commonly involved by ankylosing spondylitis, rheumatoid arthritis, and degenerative arthritis, although this involvement is often subclinical. The sternoclavicular joint may be the site of septic

arthritis, especially in injection drug users. These joints should be examined for tenderness, swelling, and bony abnormalities. Tenderness of the manubriosternal or sternocostal joints is much more frequent than actual swelling. Tenderness of these joints without actual swelling has been termed *costochondritis*; if actual swelling is present, *Tietze's syndrome* may be the term used.

Acromioclavicular Joint

The acromioclavicular joint is formed by the lateral end of the clavicle and the medial margin of the acromion process of the scapula. Arthritis of the acromioclavicular joint is most commonly attributable to trauma leading to degenerative arthritis. Bony enlargement of this joint is typically observed, but soft tissue swelling is not usually visible or palpable. Tenderness or pain with adduction of the arm across the chest indicates pathology of the acromioclavicular joint. Movement of this joint occurs with shoulder motion but is difficult to measure accurately. The acromioclavicular joint may be involved by rheumatoid arthritis or spondyloarthropathies, although these often are not severe enough to come to clinical attention.

Shoulder

See Chapter 46.

Elbow

The elbow joint is composed of three bony articulations (Figure 40-1). The principal articulation is the humeroulnar joint, which is a hinge joint. The radiohumeral and proximal radioulnar articulations allow rotation of the forearm.

To examine the elbow joint, the examiner places the thumb between the lateral epicondyle and the olecranon process in the lateral paraolecranon groove and places one or two fingers in the corresponding groove medial to the olecranon. The examiner relaxes and passively moves the elbow through flexion, extension, and rotation. One should examine the skin around the elbow joint carefully, noting abnormalities such as psoriatic plaques, rheumatoid nodules, or tophi. It is useful to palpate the olecranon bursa carefully to exclude the presence of small nodules or tophi. Limitation of motion and crepitus should be noted. Synovial swelling is most easily palpated as it bulges under the examiner's thumb when the elbow is passively extended. The synovial membrane sometimes can be palpated over the posterior aspect of the joint between the olecranon process and the distal humerus. Synovitis or effusion generally results in limitation of elbow extension.

The olecranon bursa overlies the olecranon process of the ulna. Olecranon bursitis is common after chronic local trauma and in rheumatic diseases, including rheumatoid arthritis and gout. A septic olecranon bursitis may occur. A patient who has olecranon bursitis usually presents with a swelling over the olecranon process, which is often tender and may be erythematous. Sometimes a large collection of fluid over the area is palpable as a cystic mass, often requiring aspiration and drainage. There is generally no pain with elbow movement.

Figure 40-1 Diagram of the elbow. Posterior aspect of the elbow joint showing radius and ulna in extension and the distribution of the synovial membrane in distention. (From Polley HF, Hunder GG: Rheumatologic interviewing and physical examination of the joints, ed 2, Philadelphia, 1978, WB Saunders. Used with permission of Mayo Foundation for Medical Education and Research.)

The medial and lateral epicondyles of the humerus are the sites of attachment of the common flexor and extensor tendons, controlling hand and wrist motion. Tenderness at the epicondyles without swelling or other signs of inflammation may indicate overuse tendinopathy, termed *lateral epicondylitis* (tennis elbow) and *medial epicondylitis* (golfer's elbow). In lateral epicondylitis, discomfort can be elicited by resisted supination of the forearm or resisted extension of the pronated wrist.¹⁵ In medial epicondylitis, discomfort can be elicited by resisted flexion of the supinated wrist.

To assess motor function of the elbow, flexion and extension can be assessed. The principal flexors of the elbow are the biceps brachii (nerve roots C5 and C6), brachialis (C5 and C6), and brachioradialis (C5 and C6) muscles. The principal extensor of the elbow is the triceps brachii muscle (C7 and C8). Occasionally, a patient may rupture the attachment site of one of the heads of the biceps, resulting in visible and palpable muscle swelling on the anterior upper arm.

Wrist and Carpal Joints

The wrist is a complex joint formed by many articulations between the radius, the ulna, and the carpal bones. The true wrist or radiocarpal articulation is a biaxial ellipsoid joint

formed proximally by the distal end of the radius and the triangular fibrocartilage and distally by a row of three carpal bones: scaphoid (navicular), lunate, and triquetrum (triangular). The distal radioulnar joint is a uniaxial pivot joint. The midcarpal joints are formed by the junction of the proximal and distal rows of the carpal bones. The midcarpal and carpometacarpal articular cavities often communicate. The intercarpal joints refer to the articulations between individual carpal bones.

Movements of the wrist include flexion (palmar flexion), extension (dorsiflexion), radial deviation, ulnar deviation, and circumduction. Pronation and supination of the hand and forearm occur primarily at the proximal and distal radioulnar joints. The only carpometacarpal joint that moves to a notable degree is the carpometacarpal joint of the thumb. This joint is saddle-shaped and moves in three planes. Crepitus at this joint is common because it is frequently involved in degenerative arthritis.

The wrist normally can be extended to 70 to 80 degrees and flexed to 80 to 90 degrees. Ulnar and radial deviation should allow 50 degrees (ulnar) and 20 to 30 degrees (radial) of movement. Loss of extension is the most incapacitating functional impairment of wrist motion.

The long flexor tendons of the forearm musculature cross the volar aspect of the wrist and are enclosed in the flexor tendon sheath under the flexor retinaculum (transverse carpal ligament). The flexor retinaculum and the underlying carpal bones form the carpal tunnel. The median nerve passes through the carpal tunnel superficial to the flexor tendons. The extensor tendons of the forearm musculature are enclosed by six synovial lined compartments.

The palmar aponeurosis (fascia) spreads out into the palm from the flexor retinaculum. Dupuytren's contracture is a fibrosing condition affecting palmar aponeurosis that becomes thickened and contracted and may draw one or more fingers into flexion at the metacarpophalangeal joint. The fourth finger frequently is affected first.

Swelling of the wrist may be caused by effusion or synovial proliferation, or both, of the tendon sheaths (tenosynovitis), the wrist joint, or a combination thereof. When swelling is attributable to tenosynovitis, swelling is localized to the distribution of a particular tendon sheath or compartment (i.e., ulnar swelling attributable to tenosynovitis of the flexor carpi ulnaris tendon), tends to be more localized, and moves with flexion and extension of the fingers. Articular swelling tends to be more diffuse and protrudes anteriorly and posteriorly from under the tendons.

Synovitis of the wrist is best detected by palpation of the dorsal aspect of the joint. Accurate localization of the synovial margins is difficult because of structures overlying the volar and dorsal aspects of the wrist. To examine the wrist, the examiner should palpate the joint gently between the thumbs dorsally and the fingers on the volar aspect. Thickening or frank synovial proliferation of the synovium should be noted. When this thickening or proliferation is severe, the range of motion of the wrist joint frequently is limited and associated with stress pain.

A ganglion is a cystic enlargement arising from a joint capsule. Ganglions characteristically occur at the volar or dorsal aspect of the wrist between the tendons.

Subluxation of the ulna may develop as a result of severe chronic inflammatory arthritis (Figure 40-2). The

Figure 40-2 Subluxation of the wrist. Side view of the wrist of a patient with rheumatoid arthritis. Note the prominence of the ulna.

subluxated ulna appears as a prominence on the dorsomedial wrist. Chronic irritation of the extensor tendons, primarily the fourth and fifth finger extensor tendons, may cause these tendons to rupture.

“Trigger fingers” secondary to stenosing tenosynovitis can be detected by palpating crepitus or nodules along the tendons in the palm while the patient slowly flexes and extends the fingers.¹⁶ The patient usually gives a history of the affected finger catching or locking with movement.

Tenosynovitis of the first extensor compartment, which encloses the abductor pollicis longus and extensor pollicis brevis muscles of the thumb, is known as de Quervain’s tenosynovitis. Patients complain of pain at the radial aspect of the wrist. Tenderness may be elicited by palpating near the radial styloid process. The Finkelstein test for de Quervain’s tenosynovitis is performed by asking the patient to make a fist with the thumb enclosed in the palm of the hand, then to move the wrist into ulnar deviation. Severe pain over the radial styloid is a positive finding, often indicating stretching of the thumb tendons in a stenosed tendon sheath.

Carpal tunnel syndrome results from pressure on the median nerve in the carpal tunnel. Carpal tunnel syndrome is discussed in detail in Chapter 50.

Muscle function of the wrist may be measured by testing flexion and extension and supination and pronation of the forearm. The principal flexors of the wrist are the flexor carpi radialis (nerve roots C6 and C7) and flexor carpi ulnaris (C8 and T1) muscles. Each of these muscles can be tested separately. This testing can be accomplished if the examiner provides resistance to flexion at the base of the second metacarpal bone in the direction of extension and ulnar deviation in the case of the flexor carpi radialis muscle and resistance at the base of the fifth metacarpal in the direction of extension and radial deviation in the case of the flexor carpi ulnaris muscle. The principal extensors of the wrist are the extensor carpi radialis longus (C6 and C7), extensor carpi radialis brevis (C6 and C7), and extensor carpi ulnaris (C7 and C8) muscles. The radial and ulnar extensor muscles can be tested separately. The principal supinators of the forearm are the biceps brachii (C5 and C6) and supinator (C6) muscles. The principal pronators of the forearm are the pronator teres (C6 and C7) and pronator quadratus (C8 and T1) muscles.

Metacarpophalangeal and Proximal and Distal Interphalangeal Joints

The metacarpophalangeal joints are hinge joints. Lateral collateral ligaments that are loose in extension tighten in flexion, preventing lateral movement of the digits. The extensor tendons that cross the dorsum of each joint strengthen the articular capsule. When the extensor tendon of the digit reaches the distal end of the metacarpal head, it is joined by fibers of the interossei and lumbricales muscles and expands over the entire dorsum of the metacarpophalangeal joint and onto the dorsum of the adjacent phalanx. This expansion of the extensor mechanism is known as the *extensor hood*.

The proximal and distal interphalangeal joints also are hinge joints. The ligaments of the interphalangeal joints resemble those of the metacarpophalangeal joints. When the fingers are flexed, the bases of the proximal phalanges slide toward the palmar side of the heads of the metacarpal bones. The metacarpal heads form the rounded prominences of the knuckles, with the metacarpal joint spaces situated about 1 cm distal to the apex of the prominences.

To examine the metacarpophalangeal joints, the examiner should palpate the dorsal and volar aspects of each joint in 20 to 30 degrees of flexion (Figure 40-3). The skin on the palmar surface of the hand is thick and covers a fat pad between it and the metacarpophalangeal joint. This makes palpation of the palmar surface of the joint difficult. It is especially helpful in examining the small joints to compare one with another to detect subtle synovitis. Gentle lateral compression with force applied at the base of the second and fifth metacarpophalangeal joints often elicits tenderness if synovitis is present (squeeze test).

The proximal and distal interphalangeal joints are best examined by palpating gently over the lateral and medial aspects of the joint, where the flexor and extensor tendons do not interfere with assessment of the synovial membrane. Alternatively, the joint can be compressed anteroposteriorly by the thumb and index finger of one of the examiner’s

Figure 40-3 Palpation of the metacarpophalangeal joints is done with the examiner’s thumbs palpating the dorsal aspect of the joint, while the forefingers palpate the volar aspect of the metacarpal head. The joints should be examined while the examiner holds the patient’s hand in a relaxed position of partial flexion.

hands, while the other thumb and index finger palpate for synovial distention medially and laterally. The Bunnell test is useful in differentiating synovitis of the proximal interphalangeal joints from tightening of the intrinsic muscles (see Chapter 50).

Swelling of the fingers may result from articular or peri-articular causes. Synovial swelling usually produces symmetric enlargement of the joint itself, whereas extra-articular swelling may be diffuse and may extend beyond the joint space. Asymmetric enlargement, involving only one side of the digit or joint, is less common and usually indicates an extra-articular process. Diffuse swelling of an entire digit, known by the terms *dactylitis* and *sausage digit*, may result from tenosynovitis and is seen most commonly in the spondyloarthropathies, such as reactive arthritis or psoriatic arthritis. Rheumatoid nodules are firm periarticular swellings that frequently overlie the joints or bony prominences in patients with chronic rheumatoid disease. Chronic swelling with distention of the metacarpophalangeal joints tends to produce stretching and laxity of the articular capsule and ligaments. This laxity, combined with muscle imbalance and other forces, eventually results in the extensor tendons of the digits slipping off the metacarpal heads to the ulnar sides of the joints. The abnormal pull of the displaced tendons is one of the factors that cause ulnar deviation of the fingers in chronic inflammatory arthritis (Figure 40-4).

Swan neck deformity describes a finger with a flexion contracture of the metacarpophalangeal joint, hyperextension of the proximal interphalangeal joint, and flexion of the distal interphalangeal joint. These changes are produced by contraction of the interossei and other muscles that flex the metacarpophalangeal joints and extend the proximal interphalangeal joints. This deformity is characteristic of rheumatoid arthritis but may be seen in other chronic arthritides (Figure 40-5).

Boutonnière deformity describes a finger with a flexion contracture of the proximal interphalangeal joint associated with hyperextension of the distal interphalangeal joint. The deformity is common in rheumatoid arthritis and results when the central slip of the extensor tendon of the proximal

Figure 40-4 Destructive rheumatoid arthritis. Chronic synovial pannus formation involves the metacarpophalangeal joints of both hands and both wrist joints. Subluxation and ulnar deviation are present in the right hand metacarpophalangeal joints. Swan neck deformities are present in the right third through fifth and left second through fourth digits.

Figure 40-5 Swan neck deformity in a patient with psoriatic arthritis. Note hyperextension of the proximal interphalangeal joint and hyperflexion of the distal interphalangeal joint of the second digit. Also note the psoriatic changes of the third and fourth fingernails.

interphalangeal joint becomes detached from the base of the middle phalanx, allowing palmar dislocation of the lateral bands. The dislocated bands cross the fulcrum of the joint and act as flexors instead of extensors of the joint.

Another abnormality is telescoping or shortening of the digits produced by resorption of the ends of the phalanges secondary to destructive arthropathy. This may be seen in the arthritis mutilans form of psoriatic arthritis. Shortening of the fingers is associated with wrinkling of the skin over involved joints and is called *opera-glass hand* or *la main en lorgnette*.

A mallet finger results from avulsion or rupture of the extensor tendon at the level of the distal interphalangeal joint. With this deformity, the patient is unable to extend the distal phalanx, which remains in a flexed position. This deformity frequently results from traumatic injuries.

The Murphy sign is a test for lunate dislocation. The patient is asked to make a fist. The third metacarpal head usually is more prominent than the second and fourth. If the third metacarpal is level with the second and fourth, the finding is positive for lunate dislocation.

Involvement of the distal interphalangeal joints in rheumatoid arthritis is uncommon. Bony hypertrophy and osteophyte formation are commonly seen, however, at the distal and proximal interphalangeal joints in patients with osteoarthritis. Enlarged, bony, hypertrophic distal interphalangeal joints are called *Heberden nodes*, whereas similar changes at the proximal interphalangeal joints are called *Bouchard nodes*. These usually are easily differentiated from the synovitis of inflammatory arthritis because, on palpation, the enlargement is hard or bony. In addition, signs of inflammation are minimal. Heberden and Bouchard nodes should be easily distinguished from rheumatoid nodules, but patients occasionally confuse these when describing swellings over joints. The examiner should be aware of other causes of nodules on the hands, including tophaceous gout (Figure 40-6) and, rarely, multicentric reticulohistiocytosis. The first carpometacarpal joint also is often affected in osteoarthritis (Figure 40-7).

The patient's fingernails should be inspected for evidence of clubbing or other abnormalities. Often in patients with

Figure 40-6 Gout. Note the enlargement and the tophaceous deposits visible through the skin.

psoriatic arthritis, ridging, onycholysis, or nail pitting is present. Occasionally, patients with osteoarthritis develop a groove deformity of the nail on a digit with a Heberden node. (This nail deformity has been called a *Heberden node nail*.) The abnormality is believed to occur secondary to synovial cyst encroachment on the nail bed by the evolving osteoarthritis process. With time, the nail may return to normal.

A crude but sometimes useful assessment of hand function can be made by asking the patient to make a fist. An estimate of the patient's ability to form a full fist can be recorded as a percentage fist, with 100% being a complete fist. A fist of 75% indicates that the patient can touch the palm with the fingertips. The ability to oppose fingers, especially the thumb, is crucial to hand function because of the necessity to grasp or at least pinch for objects. If the patient is unable to form a full fist, the ability or inability to pinch

Figure 40-7 Osteoarthritis of the hands. Note the advanced hypertrophic enlargement at the base of both thumbs. Both second distal interphalangeal joints are notable for advanced bony enlargement, and more moderate changes are seen in the other interphalangeal joints.

or oppose fingers can be demonstrated by asking the patient to pick up a small object.

Strength of the hands can be assessed crudely by asking the patient to grip firmly two or more of the examiner's fingers. More accurate measures of grip strength can be made by using a dynamometer or by having the patient squeeze a partially inflated sphygmomanometer (at 20 mm Hg). It sometimes is useful to test the strength of the fingers separately. The prime movers of flexion of the second through fifth metacarpophalangeal joints are the dorsal and palmar interossei muscles (nerve roots C8 and T1). The lumbricales muscles (C6, C7, and C8) flex the metacarpophalangeal joints when the proximal phalangeal joints are extended. The flexors of the proximal interphalangeal joints are the flexor digitorum superficialis muscles (C7, C8, and T1), and the flexor of the distal interphalangeal joints is the flexor digitorum profundus muscle (C7, C8, and T1).

The prime extensors of the metacarpophalangeal joints and interphalangeal joints of the second through fifth fingers are the extensor digitorum communis (nerve roots C6, C7, and C8), extensor indicis proprius (C6, C7, and C8), and extensor digiti minimi (C7) muscles. The interossei and lumbricales muscles simultaneously flex the metacarpophalangeal joints and extend the interphalangeal joints. The dorsal interossei (C8 and T1) and abductor digiti minimi (C8) muscles abduct the fingers, whereas the palmar interosseous muscles adduct the fingers.

The thumb is moved by several muscles. The prime flexor of the first metacarpophalangeal joint is the flexor pollicis brevis muscle (nerve roots C6, C7, C8, and T1). The prime flexor of the interphalangeal joint is the flexor pollicis longus muscle (C8 and T1). The metacarpophalangeal joint of the thumb is extended by the extensor pollicis brevis muscle, and the prime extensor of the interphalangeal joint is the extensor pollicis longus muscle (C6, C7, C8, and C9).

The principal abductors of the thumb are the abductor pollicis longus (nerve roots C6 and C7) and the abductor pollicis brevis (C6 and C7) muscles. Motion occurs primarily at the carpometacarpal joint. The principal adductor of the thumb is the adductor pollicis muscle (C8 and T1). Motion occurs primarily at the carpometacarpal joint. The principal movers in opposition of the thumb and fifth fingers are the opponens pollicis (C6 and C7) and opponens digiti minimi (C8 and T1) muscles.

Sensation and nerve injuries in the upper extremity are discussed in Chapters 45 and 50.

Hip

The hip is a spheroidal or ball-and-socket joint formed by the rounded head of the femur and the cup-shaped acetabulum (see Chapter 48). Stability of the joint is ensured by the fibrocartilaginous rim of the glenoid labrum and the dense articular capsule and surrounding ligaments, including the iliofemoral, pubofemoral, and ischio capsular ligaments that reinforce the capsule. Support also is provided by the powerful muscle groups that surround the hip. The principal hip flexor is the iliopsoas muscle assisted by the sartorius and rectus femoris muscles. Hip adduction is accomplished by the three adductors (longus, brevis, and magnus) plus the gracilis and pectineus muscles. The gluteus

medius is the major hip abductor, whereas the gluteus maximus and hamstrings extend the hip. Several clinically important bursae are found around the hip joint. Anteriorly, the iliopsoas bursa lies between the psoas muscle and the joint surface. The trochanteric bursa lies between the gluteus maximus muscle and the posterolateral greater trochanter, and the ischiogluteal bursa overlies the ischial tuberosity.

Examination of the hip should begin by observing the patient's stance and gait. The patient should stand in front of the examiner so that the anterior iliac spines are visible. Pelvic tilt or obliquity may be present and related to structural scoliosis, anatomic leg-length discrepancy, or hip disease.

Hip contractures may result in abduction or adduction deformities. To compensate for an adduction contracture, the pelvis is tilted upward on the side of the contracture. This allows the legs to be parallel during walking and weight bearing. With a fixed abduction deformity, the pelvis becomes elevated on the normal side during standing or walking. This elevation causes an apparent shortening of the normal leg and forces the patient to stand or walk on the toes of the normal side or to flex the knee on the abnormal leg. Viewed from behind with the legs parallel, the patient with hip disease and an adducted hip contracture may have asymmetric gluteal folds secondary to pelvic tilt, with the diseased side elevated. In this situation, the patient is unable to stand with the foot of the involved leg flat on the floor. In abduction contracture, the findings are reversed; with both legs extended and parallel, the uninvolved side is elevated.

A hip flexion deformity commonly occurs in diseases of the hip. Unilateral flexion of the hip in the standing position reduces weight bearing on the involved side and relaxes the joint capsule, causing less pain. This posture is best noted by observing the patient from the side. A hyperlordotic curve of the lumbar spine compensates for lack of full hip extension.

Gait should be assessed in the patient with possible hip joint disease. With a normal gait, the abductors of the weight-bearing leg contract to hold the pelvis level or to elevate the non-weight-bearing side slightly. Two abnormalities of gait may be commonly observed in patients with hip disease. The most common abnormality seen with a painful hip is the antalgic (limping) gait. With this gait, the individual leans over the diseased hip during the phase of weight bearing on that hip, placing the body weight directly over the joint to avoid painful contraction of the hip abductors. With a Trendelenburg gait, with weight bearing on the affected side, the pelvis drops and the trunk shifts to the normal side. Although the antalgic gait is frequently seen with painful hips and the Trendelenburg gait is seen in patients with weak hip abductors, these gaits are not specific, and either may occur as a result of hip pain from one of several causes. A mild Trendelenburg gait is seen often in normal individuals.

The Trendelenburg test assesses the stability of the hip, together with the ability of the hip abductor muscle to stabilize the pelvis on the femur.¹⁷ It is a measure of the gluteus medius hip abductor strength. The patient is asked to stand while bearing weight on only one leg. Normally, the abductors hold the pelvis level or the nonsupported side

slightly elevated. If the non-weight-bearing side drops, the test is positive for weakness of the weight-bearing side hip abductors, especially the gluteus medius muscle. This test is nonspecific and may be used in primary neurologic or muscle disorders and in hip diseases that lead to weakness of the hip abductors.

The motion of the hip should be assessed with the patient in the supine position. Range of motion of the hip includes flexion, extension, abduction, adduction, internal and external rotation, and circumduction. The degree of flexion permitted varies with the manner with which it is assessed. When the knee is held flexed at 90 degrees, the hip normally flexes to an angle of 120 degrees between the thigh and the long axis of the body. If the knee is held in extension, the hamstrings limit hip flexion to about 90 degrees. The presence of a hip flexion contracture is suggested by persistence of lumbar lordosis and pelvic tilt, masking the contracture by allowing the involved leg to remain in contact with the examination table. The Thomas test shows the flexion contracture. With this test, the opposite hip is fully flexed to flatten the lumbar lordosis and fix the pelvis. The involved leg should be extended toward the table as far as possible. Flexion contracture of the diseased hip becomes more obvious and can be estimated in degrees from full extension. Measurement for leg-length discrepancy is performed with the patient supine and the legs fully extended. Each leg is measured from the anterior superior iliac spine to the medial malleolus. A difference of 1 cm or less is unlikely to cause any abnormality of gait and may be considered normal. In addition to true leg-length asymmetries, apparent leg-length discrepancies may result from pelvic tilt or abduction or adduction contractures of the hip.

Abduction is measured with the patient supine and the leg in an extended position perpendicular to the pelvis. Pelvic stabilization is achieved by placing an arm across the pelvis with the hand on the opposite anterior iliac spine. With the other hand, the examiner grasps the patient's ankle and abducts the leg until the pelvis begins to move. Abduction to about 45 degrees is normal. It is helpful to compare one side with the other because the normal range of motion may vary. Alternatively, the examiner could stand at the foot of the table, grasp both the patient's ankles, and simultaneously abduct both legs. Abduction is commonly limited in hip joint disease. Adduction is assessed by grasping the patient's ankle and raising the leg off the examination table by flexing the hip enough to allow the tested leg to cross over the opposite leg. Normal adduction is about 20 to 30 degrees. Hip rotation may be tested with the hip and knee flexed to 90 degrees or with the leg extended. Normal hip external rotation and internal rotation are observed to 45 degrees and 40 degrees, respectively. The difference in rotation between the flexed and extended hip is attributable to increased stabilization of the joint by surrounding ligaments in the extended position. Rotation decreases with extension. To test hip rotation, the extended leg is grasped above the ankle and rotated externally and internally from the neutral position. Limitation of internal rotation of the hip is a sensitive indicator of hip joint disease.

Extension is tested with the patient in the prone position. Estimating hip extension can be difficult because some of the apparent motion arises from hyperextension of the lumbar spine, pelvis rotation, motion of the buttock soft

tissue, and flexion of the opposite hip. The pelvis and the lumbar spine can be partially immobilized by placing an arm across the posterior iliac crest and the lower lumbar spine. The examiner places the other hand under the thigh with the knee flexed and hyperextends the thigh. Normal extension ranges from 10 to 20 degrees. Limitation of extension often occurs secondary to a hip flexion contracture.

Swelling around the hip only rarely can be discerned on examination. The flexion abduction external rotation (FABER) test, also known as the Patrick test, is a commonly used screening test for intra-articular hip pathology.¹⁸ To perform this test, the examiner has the patient lie supine with the foot ipsilateral to the test hip, resting on the contralateral knee. The examiner then slowly lowers the test leg toward the examining table, applying gentle pressure to the knee of the test hip and the contralateral anterior superior iliac spine. Normally, the test leg will fall at least parallel to the opposite leg. The FABER test is considered positive when the maneuver reproduces the patient's pain. Normally, the test leg will fall at least parallel to the opposite leg. Although very sensitive for hip joint disease, this test is not specific, as a positive test may indicate iliopsoas tightness or sacroiliac joint disease.

In children, two useful screening tests for congenital hip disease are the Ortolani maneuver and the Galeazzi sign. With the Ortolani maneuver, the examiner flexes the hips and grasps the legs of a supine infant so that the examiner's thumbs are against the inner thighs and fingers are draped over the outer (lateral) side of the thighs. With gentle traction, the hips are abducted and laterally rotated. Resistance usually is felt at 30 to 40 degrees of lateral rotation and abduction. With a positive result of the Ortolani test, a click is felt before abduction to the normal 70 degrees. The Ortolani test should not be done repeatedly because it can lead to damage of the articular cartilage on the femoral head. The Galeazzi sign is useful for assessing unilateral congenital hip dislocation in children younger than 18 months. The child is placed supine with the knees and hips flexed to 90 degrees. Both knees should normally reside at the same level, and a positive test result is indicated if one knee is higher than the other.

The iliotibial band is a part of the fascia lata extending from the iliac crest, sacrum, and ischium over the greater trochanter to the lateral femoral condyle, tibial condyle, and fibular head, and along the lateral intermuscular system, separating the hamstrings from the vastus lateralis muscle. The tensor fasciae latae muscle may produce an audible snap as it slips over the greater trochanter if the weight-bearing leg moves from hip flexion and adduction to a neutral position, as in climbing stairs. Most commonly observed in young women, the snapping hip usually does not cause severe pain. The Ober test evaluates the iliotibial band for contracture. The patient lies on the side, with the lower leg flexed at the hip and knee. The examiner abducts and extends the upper leg with the knee flexed at 90 degrees. The hips should be slightly extended to allow the iliotibial band to pass over the greater trochanter. The examiner slowly lowers the limb with the muscles relaxed. A positive test result indicative of an iliotibial band contracture occurs if the leg does not fall back to the level of the table top.

A common cause of lateral hip pain is trochanteric bursitis. Patients with this condition often complain of pain

and tenderness when they attempt to lie on the affected side or climb stairs. The greater trochanter should be palpated for tenderness and compared with the opposite side. In trochanteric bursitis, this area is usually exquisitely tender. The pain of trochanteric bursitis is aggravated by actively resisted abduction of the hip. Aching and tenderness over the buttock area may be secondary to an ischial bursitis. Other causes of lateral and posterior hip (buttock) discomfort include pain at muscle and tendon insertion sites.

Anterior hip and groin pain may be secondary to hip abnormality, most commonly degenerative arthritis. Decreased range of motion should be noted in these patients. Other causes include iliopsoas bursitis, in which swelling and tenderness may be noted in the middle third of the inguinal ligament lateral to the femoral pulse. This pain is aggravated by hip extension and is reduced by flexion. The bursitis may be a localized problem or may represent extension of hip synovitis. It usually is impossible to distinguish between a localized bursitis and an extension of hip synovitis on the basis of the physical examination. If the patient is tender in the region of the iliopsoas bursa, but no swelling is palpable, the examiner should consider tendinitis of the iliopsoas muscle. The inguinal region should be palpated for other abnormalities, such as hernias, femoral aneurysms, adenopathy, tumor, and psoas abscess or masses.

Muscle strength testing should include the hip flexors, extensors, abductors, and adductors. The primary hip flexor is the iliopsoas muscle (nerve roots L2 and L3). Flexion may be tested with the patient sitting at the edge of a table. The examiner exerts downward pressure against the thigh proximal to the knee while the patient attempts to flex the hip. The pelvis may be stabilized by the examiner's other hand placed on the ipsilateral iliac crest. Alternatively, with the patient supine and holding the leg in 90 degrees of flexion at the hip, the examiner may attempt to straighten the hip.

Hip extension is tested with the patient lying prone. The primary hip extensor is the gluteus maximus muscle (L5 and S1). With the knee flexed to remove hamstring action, the patient is instructed to extend the hip and thigh off the surface of the table as the examiner places a forearm across the posterior iliac crest to stabilize the pelvis and applies downward pressure to prevent the lateral trunk muscles from elevating the pelvis and leg off the table.

Abduction may be tested with the patient prone or supine. The patient should abduct the thigh and leg against resistance from the examiner applied at the midthigh level.

The primary adductor is the adductor longus muscle (nerve roots L3 and L4). The examiner holds the upper leg proximal to the knee in slight abduction, while the patient resists and attempts to adduct the leg. Testing for abduction and adduction also may be done in the two legs simultaneously. The patient lies supine with the legs fully extended and the hips moderately abducted. To test abduction, the patient actively pushes out against the examiner's resistance against the lateral malleoli. Adduction is tested by movement against resistance at the medial malleoli.

Knee

The knee is a compound condylar joint with three articulations: the patellofemoral and the lateral and medial tibiofemoral condyles with their fibrocartilaginous menisci. The

knee is stabilized by its articular capsule, the patellar ligament, medial and lateral collateral ligaments, and anterior and posterior cruciate ligaments. The collateral ligaments provide medial and lateral stability, whereas the cruciates provide anteroposterior and rotatory stability. Normal knee motion is a combination of flexion or extension and rotation. With flexion, the tibia internally rotates, and with extension, it externally rotates on the femur. The surrounding synovial membrane is the largest of the body's joints; it extends 6 cm proximal to the joint as the suprapatellar pouch beneath the quadriceps femoris muscle. Several important bursae are found around the knee, including the superficial prepatellar bursa, the superficial and deep infrapatellar bursae, the pes anserine bursa distal to the medial tibial plateau, and the posterior medial semimembranous and posterolateral gastrocnemius bursae. Knee extension is primarily mediated by the quadriceps femoris muscle; knee flexion is mediated by the hamstrings. The biceps femoris muscle externally rotates the lower leg on the femur, whereas the popliteus and semitendinous muscles mediate internal rotation.

In taking the history of a patient with knee complaints, the patient should be asked about symptoms of locking, catching, or giving way. *Locking* is the sudden loss of ability to extend the knee; it usually is painful and may be associated with an audible noise, such as a click or pop. It often implies extensive intra-articular abnormality, including loose bodies or cartilaginous tears. *Catching* refers to a subjective sensation of the patient that the knee might lock; the patient may experience a momentary interruption in the smooth range of motion of the joint but is able to continue with normal motion after this brief hesitation. Catching usually implies less abnormality than true locking and may occur in various pathologic conditions. True give-way indicates that the knee actually buckles and gives out in certain positions or with certain activities. It is important to elicit details of the history to verify this common subjective complaint. Patients often experience a sensation that the knee will give out when it actually does not. Other patients say their knees are “giving out” to describe severe pain that necessitates stopping an activity. True give-way implies severe intra-articular abnormality, such as an unstable joint from ligamentous injury or incompetence.

Examination of the knees should always include observation of the patient while standing and walking. Deviation of the knees, including genu varum (lateral deviation of the knee joint with medial deviation of the lower leg), genu valgum (medial deviation of the knee with lateral deviation of the lower leg), and genu recurvatum, is most easily appreciated with the patient standing. The patient also should be observed ambulating for evidence of gait abnormalities.

Inspection should be done with the patient standing and supine. It is essential to compare side to side, noting any asymmetry that may be caused by swelling or muscle atrophy. Suprapatellar swelling with fullness of the distal anterior thigh that obliterates the normal depressed contours along the sides of the patella usually indicates knee joint effusion or synovitis. Localized swelling over the surface of the patella is generally secondary to prepatellar bursitis (Figure 40-8). Patellar alignment should be noted, including high-riding or laterally displaced patellae. The examiner also should inspect the knee from behind to identify popliteal

Figure 40-8 Prepatellar bursitis. **A**, Note the cystic swelling overlying the right patella with the appearance of two separate compartments of bursal swelling. **B**, High-resolution ultrasound image of the same patient showing collection of anechoic fluid with an internal septation.

swelling due to a popliteal or Baker cyst, most commonly caused by medial semimembranous bursal swelling. If the calves appear asymmetric, calf circumference should be measured and compared bilaterally. Popliteal cysts may rupture and dissect down into the calf muscles, resulting in enlargement and palpable fullness. Edema may be present if the cyst causes secondary venous or lymphatic obstruction. Acute rupture and dissection of a popliteal cyst can mimic thrombophlebitis, with local pain, heat, redness, and swelling. This is probably a more common cause of unilateral calf swelling in patients with rheumatoid arthritis than is deep venous thrombosis. The two conditions may be difficult to distinguish on physical examination alone.

Quadriceps femoris muscle atrophy usually develops in chronic arthritis of the knee. Atrophy of the vastus medialis muscle is the earliest change and may be appreciated by comparing the two thighs for medial asymmetry and circumference. Measurement of the thigh circumference should be performed at 15 cm above the knee to avoid spurious results due to suprapatellar effusions.

Palpation of the knee should be performed with the joint relaxed. This usually is best accomplished with the patient supine and the knees fully extended and not touching. Palpation should begin over the anterior thigh approximately 10 cm above the patella. To identify the superior margin of the suprapatellar pouch, which is an extension of the knee joint cavity, the examiner should palpate the anterior thigh, moving distally toward the knee. Swelling, thickening, nodules, loose bodies, tenderness, and warmth should be noted. A thickened synovial membrane has a boggy, doughy consistency, which differs from the surrounding soft tissue and muscle. It usually is palpated earlier over the medial aspect of the suprapatellar pouch and the medial tibiofemoral joint. To enhance detection of knee fluid, any fluid in the suprapatellar pouch is compressed with the palm of the hand placed just proximal to the patella. The synovial fluid forced into the inferior distal articular cavity is palpated with the opposite thumb and index finger laterally and medially to the patella. If the examiner alternates compression and release of the suprapatellar pouch, the synovial thickening can be differentiated from a synovial effusion. An effusion intermittently distends the joint capsule under the thumb and index finger of the opposite hand, whereas synovial thickening does not.

The examiner should not compress the suprapatellar pouch too firmly or push the tissues distally because the patella or normal soft tissue, including the fat pads, fills the palpated space and could be misinterpreted as synovitis or joint swelling. With a large effusion, the patella can be balled by pushing it posteriorly against the femur with the right forefinger, while maintaining suprapatellar compression with the left hand.

At the other extreme, effusions 4 to 8 mL can be detected by eliciting the bulge sign. This test is performed with the knee extended and relaxed. The examiner strokes or compresses the medial aspect of the knee proximally and laterally with the palm of a hand to move fluid from the area. The lateral aspect of the knee is tapped or stroked, and a fluid wave or bulge appears medially (Figure 40-9). A so-called spontaneous bulge sign occurs if, on compression along the medial side of the joint space, fluid reaccumulates with no pressure or compression along the lateral side of the joint.

The medial and lateral tibiofemoral joint margins are palpated for tenderness and bony lipping or exostosis, as can be seen in degenerative joint disease. Joint margins can be palpated easily with the hip flexed to 45 degrees, the knee flexed to 90 degrees, and the foot resting on the examining table. Tenderness localized over the medial or lateral joint margins may represent articular cartilage disease, medial or lateral meniscal abnormality, or medial or lateral collateral ligament injury. Other causes of tenderness include pathologic conditions in the underlying bony structures.

Bursitis is another cause of localized tenderness around the knee; the two most common sites are the pes anserine and the prepatellar bursae. Exquisite local tenderness usually can be elicited if bursitis is present. Mild swelling also may be appreciated. Occasionally, the prepatellar bursa can become quite swollen. It is important not to interpret this swelling mistakenly as knee joint synovitis. The two can be differentiated because the bursal margins can be outlined by

Figure 40-9 Demonstration of the bulge sign for a small synovial knee effusion. The medial aspect of the knee has been stroked to move the synovial fluid from this area (shaded depressed area in **A**). **B** shows a bulge in the previously depressed area after the lateral aspect of the knee has been tapped.

palpation; other features of true joint effusion, such as the bulge sign, are absent.

Patellofemoral malalignment is another common cause of knee pain. It is more common in female patients because of the wider Q angle caused by the broader female pelvis. The Q angle is the angle formed between the quadriceps and the patellar tendon. Patients with patellofemoral disease may complain of stiffness in the knee after a period of flexion (the moviegoer sign) or may have particular difficulty with stair climbing. Some patients may experience a sensation of catching as the patella moves over the distal femur. Patellar palpation is best performed with the knee extended and relaxed. The patella is compressed and moved so that its entire articular surface comes into contact with the underlying femur. Slight crepitation may be observed in many normally functioning knees. Pain with crepitation may suggest patellofemoral degenerative arthritis or chondromalacia patellae.

Retropatellar pain occurring with active knee flexion and extension and secondary to patellofemoral disease may be differentiated from tibiofemoral articular pain. To test this, the examiner should attempt to lift the patella away from the knee, while passively moving the knee through the range of motion. Painless motion during this maneuver indicates that the patellofemoral joint is the likely source of the pain. In addition, the “patellar grind” test is useful in patients with extensive patellofemoral abnormality. In this test, the examiner compresses the patella distally away from the femoral condyles, while instructing the patient to contract the quadriceps isometrically. Sudden patellar pain and

quadriceps relaxation indicate a positive test result. This test has frequent false-positive results, however.

Patellar stability should be assessed. The Fairbanks apprehension test is done with the patient supine, the quadriceps relaxed, and the knee in 30 degrees of flexion. The examiner slowly pushes the patella laterally. A sudden contraction of the quadriceps and a distressed reaction from the patient constitute a positive apprehension test result. A patient who has had previous patellar dislocations usually has a positive apprehension test result. The patella also can be examined for subluxation while the knee is moved through a range of motion from full flexion to extension.

The plica syndrome occasionally causes symptoms that suggest patellofemoral disease. Plicae are bands of synovial tissue, most often located on the medial side of the knee. If present, a tender band-like structure may be palpated parallel to the medial border of the patella. During flexion and extension, palpable or audible snapping may be heard, and the patient may experience symptoms of catching. Many plicae are asymptomatic, however, and they are common, so they may be considered a normal variant.

The normal knee range of motion should be from full extension (0 degrees) to full flexion of 120 to 150 degrees. Some normal individuals may be able to hyperextend to 15 degrees. Loss of full extension that is generally reversible frequently occurs with a knee joint effusion, synovitis, or both. However, permanent loss of extension due to flexion contracture is a common finding that accompanies chronic arthritis of the knee. In advanced arthritis, such as in some cases of rheumatoid arthritis, posterior subluxation of the tibia on the femur may be observed.

Ligamentous instability is tested by applying valgus and varus stress to the knee and by using the drawer test. The knee should be extended and relaxed. The examiner performs the abduction or valgus test by stabilizing the lower femur, while placing a valgus stress on the knee by abducting the lower leg with the other hand placed proximal to the ankle. A medial joint line separation with the knee fully extended indicates a tear of the medial collateral ligament plus the posterior cruciate ligament. The test is performed with the knee in 30 degrees of flexion. If the test is negative at 0 degrees, but positive at 30 degrees, the instability represents a tear of the medial collateral ligament with the posterior cruciate ligament remaining intact. The adduction or varus test is performed with the knee extended and again at 30 degrees of flexion. Separation of the lateral joint line indicates a lateral collateral ligament tear—associated or not associated with a posterior cruciate ligament tear.

The degree of ligamentous laxity observed during testing can be graded on a scale of 1 to 3. Mild or grade 1 instability indicates that the joint surfaces separate by 5 mm or less; for moderate or grade 2 instability, a separation of 5 to 10 mm is seen. Grade 3 instability is a separation greater than 10 mm. In cases of trauma, opening of the joint space indicates ligamentous instability secondary to rupture or stretching of the ligaments. In cases of chronic arthritis of the tibiofemoral compartment, medial or lateral separation may be apparent as a result of the “pseudolaxity” created by loss of cartilage and bone. If the ligaments are intact, the resulting degree of valgus or varus displacement with stressing is not any greater than in the normal knee.

The drawer test is performed with the hip flexed to 45 degrees and the knee flexed to 90 degrees. To stabilize the knee, the examiner either sits on the foot while grasping the posterior calf with both hands or supports the lower leg between his or her lateral chest wall and forearm. The anterior drawer test is performed by pulling the tibia forward. More than 6 mm of movement is abnormal and may indicate an anterior cruciate tear or laxity. Anterior subluxation may represent more complex instability, however. Rotatory instability of the knee also may exist. A positive result of the anterior drawer test, in which the lateral tibial plateau subluxates forward while the medial stays in normal position, can represent anterolateral rotatory instability. If both plateaus subluxate, tears of the middle third of the medial lateral capsular ligaments may be present. If the subluxation is not present with the tibia internally rotated, the posterior cruciate ligament is intact. A positive result of the anterior drawer test with the leg in external rotation represents a tear of the medial capsular ligament.

The Lachman test is a modification of the anterior drawer sign and tests for one-plane anterior instability.¹⁹ At least six variations of this test have been described. In the test as originally described, the patient lies supine with the tested knee between full extension and 15 degrees of flexion. The femur is stabilized with a hand of the examiner while the hand pulls the proximal aspect of the tibia forward. A positive test result is indicated by a soft feel rather than a firm end point when the tibia moves forward on the femur. A positive result of the Lachman test may indicate an anterior cruciate injury or abnormality in the posterior oblique ligament or arcuate popliteus complex. A posterior drawer test may be done with the patient positioned as for an anterior drawer test, but the examiner pushes the tibia toward the patient. A positive test result suggests damage to the posterior cruciate ligament.

During the complete joint examination, tests for meniscal injury should be performed. Symptoms suggesting a meniscal tear include locking during joint extension, clicking or popping during motion, and localized tenderness along the medial or lateral joint line. To examine the menisci, the medial and lateral joint line should be palpated with the lower leg internally rotated and the knee flexed to 90 degrees. Localized tenderness over the medial or lateral joint line suggests involvement of the medial or lateral meniscus. The McMurray test evaluates for evidence of meniscal tear, especially in the posterior half of the menisci. The patient's knee is placed in full flexion, and the examiner places a hand over the knee with the fingers along the side of the knee over the joint line and the thumb along the other side. The other hand holds the leg at the ankle and is used to rotate the lower leg medially and to apply varus stress. This test can be done repeatedly, with the knee in gradually decreasing degrees of flexion. A palpable or audible snap suggests a tear of the medial meniscus. The test can be done in a similar fashion by laterally rotating the tibia and applying valgus stress to test for a lateral meniscal injury. A positive result of a lateral test may represent a tear of the popliteus tendon, which can accompany a lateral meniscal tear.

The Apley grind test also evaluates for a torn meniscus.²⁰ With the patient lying prone and the knee flexed to 90 degrees, the examiner places downward compression on the

foot, while medially and then laterally rotating the tibia on the femur. Pain elicited during this maneuver suggests a meniscal tear.

The examiner performs the distraction test by placing his or her knee on the patient's posterior thigh to stabilize the leg while applying an upward distractive force on the foot. Pain from rotating the tibia suggests ligament damage.

A simple hyperflexion test is a useful screening test for meniscal damage. If the examiner is able to hyperflex the knee to more than 135 degrees without eliciting pain, it is unlikely that serious cartilaginous injury is present. If pain occurs with hyperflexion, the patient sometimes is able to localize it medially or laterally, which often correlates with the location of the meniscal injury. Although helpful, none of these tests for meniscal injury is completely reliable when verified by arthroscopy. Tenderness along the joint line is most sensitive but is less specific than manipulative tests such as the McMurray test.

Muscle strength testing includes testing flexion supplied by the hamstrings (i.e., the biceps femoris, semitendinosus, and semimembranosus) (nerve roots L5 to S3) and extension supplied by the quadriceps femori (L2, L3, and L4). The hamstrings are tested best with the patient prone and attempting to move the knee from 90 degrees to maximal flexion. The ankle should be kept in neutral position or dorsiflexed to remove gastrocnemius action. With the leg externally rotated, the biceps femoris, which inserts on the fibula and lateral tibia, is primarily tested, whereas flexion with internal rotation tests the semitendinosus and semimembranosus muscles, which insert on the medial side of the tibia. Extension is tested with the patient sitting upright with the knee fully extended. The examiner stabilizes the thigh with downward pressure just proximal to the knee and places downward pressure at the ankle to test the knee extensors.

Ankle

The true ankle is a hinged joint, and movement is limited to plantar flexion and dorsiflexion. It is formed by the distal ends of the tibia and fibula and the proximal aspect of the

body of the talus. Inversion and eversion occur at the subtalar joint (see Chapter 49). The tibia forms the weight-bearing portion of the ankle joint, whereas the fibula articulates on the side of the tibia. The malleoli of the tibia and fibula extend downward beyond the weight-bearing part of the joint and articulate with the sides of the talus. The malleoli provide medial and lateral stability by enveloping the talus in a mortise-like fashion. The articular capsule of the ankle is lax on the anterior and posterior aspects of the joint, allowing extension and flexion, but it is tightly bound bilaterally by ligaments. The synovial membrane of the ankle on the inside of the capsule usually does not communicate with any other joints, bursae, or tendon sheaths.

The medial and lateral ligaments surrounding the ankle contribute to medial and lateral stability of the joint. The deltoid ligament, the only ligament on the medial side of the ankle, is a triangle-shaped fibrous band that resists eversion of the foot. It may be torn in eversion sprains of the ankle. The lateral ligaments of the foot consist of three distinct bands forming the posterior talofibular, the calcaneofibular, and the anterior talofibular ligaments. These ligaments may be injured in inversion sprains of the ankle.

All tendons crossing the ankle joint lie superficial to the articular capsule and are enclosed in synovial sheaths for part of their course across the ankle. On the anterior aspect of the ankle, the tendons and the synovial tendon sheaths of the tibialis anterior, extensor digitorum longus, peroneus tertius, and extensor hallucis longus muscles overlie the articular capsule and synovial membrane. On the medial side of the ankle, posterior and inferior to the medial malleolus, lie the flexor tendons and tendon sheaths of the tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles (Figure 40-10). All three of these muscles plantar flex and supinate the foot. The tendon of the flexor hallucis longus is located more posteriorly than the other flexor tendons and lies beneath the Achilles tendon for part of its course. The calcaneus tendon (Achilles tendon), the common tendon of the gastrocnemius and soleus muscles, inserts into the posterior surface of the calcaneus, where it is subject to external trauma, various inflammatory

Figure 40-10 Diagram of the ankle. Medial aspect of the ankle shows the relationship between tendons, ligaments, artery, and nerve. (From Polley HF, Hunder GG: *Rheumatologic interviewing and physical examination of the joints*, ed 2, Philadelphia, 1978, WB Saunders. Used with permission of Mayo Foundation for Medical Education and Research.)

reactions, and irritations from bone spurs beneath it. On the lateral aspect of the ankle, posterior and inferior to the lateral malleolus, a synovial sheath encloses the tendons of the peroneus longus and peroneus brevis. These muscles extend the ankle (plantar flex) and evert (pronate) the foot. Each of the tendons adjacent to the ankle may be involved separately in traumatic or disease processes.

Three sets of fibrous bands or retinacula hold down the tendons that cross the ankle in their passage to the foot. The extensor retinaculum consists of a superior part (transverse crural ligament) in the anterior and inferior portions of the leg and an inferior part in the proximal portion of the dorsum of the foot. The flexor retinaculum is a thickened fibrous band on the medial side of the ankle. On the lateral side of the ankle, the peroneal retinaculum forms a superior and an inferior fibrous band. These bands bind down tendons of the peroneus longus and peroneus brevis muscles as they cross the lateral aspect of the ankle.

Synovial swelling of the ankle joint is most likely to cause fullness over the anterior or anterolateral aspect of the joint because the capsule is more lax in this area. Mild swelling of the joint may not be apparent on inspection because of the many structures crossing the joint superficially. Efforts should be made to differentiate superficial linear swelling localized to the distribution of the tendon sheaths from more diffuse fullness and swelling attributable to involvement of the ankle joint. Swelling of the heels may be observed from behind the standing patient and may be caused by enthesitis of the Achilles tendon insertion, which can occur in spondyloarthropathies (Figure 40-11).

It is difficult to observe synovitis of the intertarsal joints. Intertarsal joint synovitis may produce an erythematous puffiness or fullness over the dorsum of the foot.

From the normal position of rest in which there is a right angle between the leg and the foot, labeled 0 degrees, the ankle normally allows about 20 degrees of dorsiflexion and about 45 degrees of plantar flexion. Inversion and eversion of the foot occur mainly at the subtalar and other intertarsal

joints. From the normal position of the foot, the subtalar joint normally permits about 20 degrees of eversion and 30 degrees of inversion. To test the subtalar joint, the examiner grasps the calcaneus with a hand and attempts to invert and evert it, holding the ankle motionless.

A general assessment of muscular strength of the ankle can be obtained by asking the patient to walk on toes and on heels. If the patient can walk satisfactorily on the toes and on the heels, the muscle strength of the flexors and extensors of the ankle can be considered normal. If this cannot be accomplished, it is desirable to test the muscles individually.

The principal flexors of the ankle are the gastrocnemius (nerve roots S1 and S2) and the soleus (S1 and S2) muscles. The principal extensor (dorsiflexors) of the ankle is the tibialis anterior muscle (L4, L5, and S1). The tibialis posterior muscle (L5 and S1) is the principal inverter. To test the tibialis posterior muscle, the foot should be in plantar flexion. The examiner applies graded resistance on the medial border of the forefoot while the patient attempts to invert the foot. The principal everters of the foot are the peroneus longus (L4, L5, and S1) and peroneus brevis (L4, L5, and S1) muscles.

KEY POINTS

Inflammatory arthritis causes morning stiffness and pain with restricted joint movement.

Pain worsening after movement usually indicates mechanical joint pain.

Soft tissue disorders usually produce pain in a periarticular distribution.

Acute monoarthritis presentations (developing suddenly) are usually related to trauma.

Monoarthritis (developing over 1 to 2 days) presentation is usually inflammation- or infection-related.

Chronic monoarthritis presentation indicates pre-existing joint disease, but causes of acute monoarthritis need to be excluded.

Synovial fluid analysis is the most valuable laboratory test in acute monoarthritis.

The sudden onset of monoarthritis in a synovial joint is a significant clinical event. The most serious cause is joint infection because of associated mortality ($\approx 15\%$) and probability of impaired long-term function. However, the commonest of the differential diagnoses (Table 41-1) is trauma or inflammation. Each presentation of monoarthritis requires immediate investigation and treatment to limit pain and prevent joint destruction. The British Society of Rheumatology and British Orthopaedic Association generated guidelines (Figure 41-1) to assist physicians in the diagnosis of the acutely swollen joint¹ based on history, examination, radiologic, and blood and synovial investigations.

Monoarthritis can also be a new presentation of more chronic forms of arthritis, and monoarticular pain can result from noninflammatory arthropathies, periarticular problems, and bone and soft tissue disorders. These are discussed in the context of a formal differential diagnosis.

HISTORY

One should examine the patient's age, occupation, and social, drug, travel, and sexual history. Pain and joint stiffness, its diurnal variation, and aggravating and relieving factors should be sought, and a history of swelling should be established. Specific features of relevance include trauma, joint locking, and presence of systemic symptoms (fevers, sweats, rigors, and weight loss). Inquiring about ocular, oral,

Acute Monoarthritis

MAX FIELD

respiratory, gastrointestinal, or skin symptoms can facilitate the diagnosis. Inquiring about ocular, oral, respiratory, gastrointestinal, or skin symptoms can facilitate the diagnosis if the monoarthritis is a presentation of a chronic arthropathy, related inflammatory disease, postinfectious phenomenon, or connective tissue disease. Table 41-2 summarizes symptoms and signs that characterize patients with inflammatory or noninflammatory joint disease and soft tissue disorders² to help initial evaluation.

EXAMINATION

The Regional Examination of the Musculoskeletal System (REMS) can be used to identify monoarticular abnormalities.³ Physicians should look, feel, and move joints to assess function—comparing the affected joint and normal side and for evidence of more widespread disease. In any acutely swollen joint, examination should include looking for local signs of inflammation (pain, erythema, swelling, heat, and loss of function). Any patient with preceding arthritis should be assessed for chronic changes to joint structure and disability. Local synovial swelling and/or effusion, joint instability, limited movement, and deformity of any single joint necessitate detailed investigation. Local monoarticular tenderness without swelling could indicate enthesitis, tendinitis, bursitis, or bone disease. A complete examination should look specifically for ocular signs, skin rashes, ulcers, and nodules.

INVESTIGATIONS

Blood

Inflammatory, septic, and crystal arthritides cause elevated erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and white cell count (WCC), often associated with anemia. Systemic disease involvement is assessed by renal, liver, muscle, or bone biochemical screening and protein electrophoresis. Raised uric acid levels suggest a diagnosis of gout. In acute hemarthrosis, a platelet count, international normalized ratio, and clotting studies are warranted. Blood cultures are mandatory in patients with suspected septic arthritis and should precede antibiotic prescription. Viral screening (IgG and IgM antibodies), antistreptolysin-O test (ASOT), and Lyme serology can be diagnostic in relevant situations.

Rheumatoid factor and antinuclear antibodies (ANAs) suggest rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE), but autoantibodies can be present in infectious diseases, in other autoimmune diseases, and in normal individuals. Similar limitations apply to results for

Table 41-1 Causes of Acute Joint or Periarticular Pain*

Common Acute Monoarthritis
Septic arthritis (nongonococcal, gonococcal)
Crystal arthritis (gout, pseudogout)
Reactive arthritides
Lyme disease
Plant thorn synovitis
Other infections (mycobacterial, viral, soft tissue)
Trauma or Internal Derangement
Loose bodies
Stress fractures
Ischemic necrosis
Hemarthrosis
Acute Monoarthritis of Polyarthritis
Psoriatic arthritis
Enteropathic arthritis
Rheumatoid arthritis/palindromic rheumatism
Juvenile inflammatory arthritides
Monoarthropathies from Noninflammatory Disease
Osteoarthritis
Charcot's joints
Storage diseases (hemochromatosis, ochronosis)
Synovial Diseases
Pigmented villonodular synovitis
Lipoma arborescens
Synovial osteochondromatosis
Reflex sympathetic dystrophy
Sarcoidosis
Amyloid
Acute Monoarthritis of Systemic Disease
Systemic lupus erythematosus
Vasculitides (antineutrophil cytoplasmic antibody positive and negative)
Henoch-Schönlein purpura
Behçet's disease
Bacterial endocarditis
Familial Mediterranean fever
Relapsing polychondritis
Soft Tissue Lesions
Bone Diseases
Paget's disease
Osteomyelitis (Brodie's abscess)
Osteogenic/osteoid tumors
Metastatic disease
Pulmonary hypertrophic osteoarthropathy

*This table shows the causes of inflammation in any one joint (monoarthritis) and pain around the joint that presents without inflammation (monoarthropathy).

antineutrophil cytoplasmic antibodies (ANCA) and angiotensin-converting enzyme (ACE), so positive results should be applied in the clinical context. Anti-cyclic citrullinated protein (CCP) antibodies are sensitive for RA and are useful in early presentation. Other relevant blood tests include thyroid function, ferritin, and vitamin D level and analysis of human leukocyte antigen (HLA) genes.

Urine

The urinary tract can be a source of gram-negative bacteria in septic arthritis in the elderly. Significant proteinuria and/or hematuria and red cell casts indicate renal damage in SLE, vasculitis, or subacute bacterial endocarditis.

Imaging Studies

A range of imaging studies assist in diagnosis of acute monoarthritis.⁴

1. Plain radiographs identify soft tissue swelling, calcium in periarticular tissues, fractures, local bone disease, and loose bodies, as well as destructive changes in long-standing arthritides.
2. Computed tomography (CT): CT scanning better identifies fractures, bone diseases, and intra-abdominal and chest pathology. It is useful when magnetic resonance imaging (MRI) is contraindicated. In acute arthritis, CT scan can show osteomyelitis over and above acute inflammation.
3. Musculoskeletal ultrasound (US): US is increasingly reliable for use in rheumatology practice provided practitioners are appropriately trained.⁴ US is quick, efficient, and cheap and as effective as MRI and clinical examination in detecting synovitis⁵ and soft tissue damage in acute shoulder injury.⁶ In acute monoarthritis US can show loculated synovial fluid to better target aspiration and injection,⁷ and power Doppler views can demonstrate increased blood flow in active synovitis.⁸ US is recommended for detection of synovitis by the European League Against Rheumatism (EULAR) in early arthritis.⁹
4. MRI: Although it is the best technique for soft tissue imaging, MRI is time consuming and costly. MRI can diagnose internal ligament damage and tendon enthesitis and is most effective in identifying avascular necrosis of bone. MRI is also useful when identifying the extent of inflammation in acute monoarthritis and subclinical joint involvement. EULAR also suggests MRI for diagnosis of acute early arthritis.⁹
5. Arthrography: Imaging internal joint structure after injection of radiopaque solutions in association with CT scanning is useful for hip cartilage tears and in situations when MRI is not feasible.
6. Radionuclide scans. Bone scanning with technetium-labeled methylene diphosphonate identifies osteoid osteomas, bone sarcomas, bony metastases, osteomyelitis, and stress fractures not seen on plain radiographs. Bone scintigraphy is helpful when excluding bone and joint disorders in patients with chronic pain syndromes. Although not specific in acute arthritides, bone scans show differences in the pattern of joint involvement between inflammatory conditions and osteoarthritis. Labeled white cell scans can identify areas of infection, especially when the source of infection is uncertain in patients with septic arthritis.

Synovial Fluid

The most useful test in acute monoarthritis is examination of synovial fluid, which should be analyzed for color and cloudiness (Table 41-3). One should use microscopy to characterize the predominant cells, Gram stain to detect bacteria, and polarized light analysis to identify uric acid or calcium pyrophosphate dehydrate (CPPD) crystals.¹ Identification of bacteria following synovial fluid culture can provide results even when a Gram stain is negative.

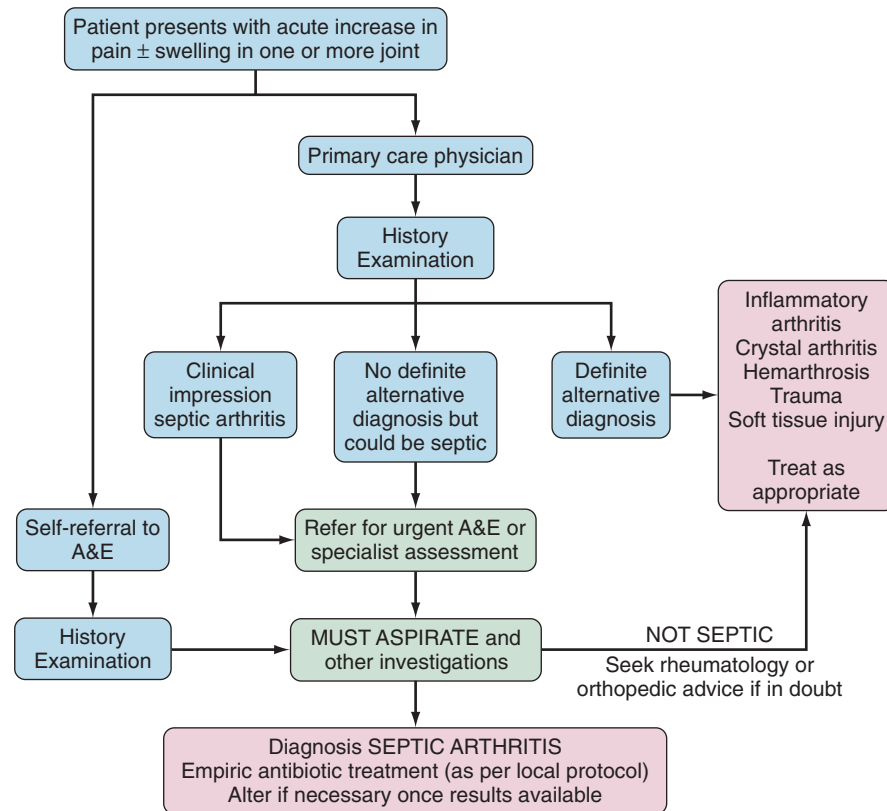

Figure 41-1 British Society for Rheumatology and British Orthopaedic Association guidelines for management of the acutely swollen joint.¹ A&E, accident and emergency department.

Neisseria organisms are fastidious with low yields from culture, but polymerase chain reaction (PCR) can detect *Neisseria*-specific deoxyribonucleic acid (DNA).

Many centers measure synovial fluid WCC, which may differentiate inflammatory and noninflammatory presentations but crucially fails to differentiate between inflammation and infection. Low synovial fluid glucose and high lactate¹⁰ and procalcitonin¹¹ are found in septic arthritis, but evidence that these can separate infectious from inflammatory arthritis in a clinically meaningful way is limited. Bacterial identification in synovial fluid from patients with

septic arthritis can be inhibited by prior antibiotic use, and hence a careful drug history should be elicited.¹² CPPD crystals are difficult to detect, so in both cases a clinical diagnosis should not be excluded if symptoms, signs, and investigations are suggestive.

Synovial or Bone Biopsy

Arthroscopic synovial biopsy is rarely necessary, but in tuberculosis, sarcoidosis, amyloid, pigmented villonodular synovitis, lipoma arborescens, and foreign body synovitis it

Table 41-2 Symptoms and Signs from Which Patients Complain When Having Inflammatory Joint Pain Such as Septic Arthritis, Noninflammatory Joint Pain Such as Osteoarthritis, and Soft Tissue Problems Such as Tendinitis or Bursitis*

Feature	Inflammatory Joint Pain	Noninflammatory Joint Pain	Soft Tissue Injury Tendon/Bursa, etc.
Symptoms			
Morning stiffness	Usually > 30 min	Local usually < 30 min	Localized and brief
Constitutional symptoms	Present (fever, malaise)	None	None
Time of major discomfort	After prolonged inactivity	After prolonged use	During and after use
Locking/instability	Unlikely in acute joint disease	Suggests internal joint derangement	Unusual unless tendon damage/tear present
Signs			
Swelling	Common	Can be bone	Unusual
Tenderness	Diffuse over joint space	Mild over joint line	Localized periarticular
Inflammation	Common	Unusual	Over tendon/bursa
Instability	Uncommon	Occasional	Uncommon
Multisystem disease	More common	No	Unusual

*Adapted from 1996 ACR guidelines for evaluation of adults with acute musculoskeletal symptoms.

Table 41-3 Synovial Fluid Characteristics in the Clinical Situations, with Imaging and Investigation Techniques Best Used to Identify the Cause

Diagnosis	Cells	Microorganisms	Appearance	Imaging Modality	Comments
Bacterial arthritis	Neutrophils 10,000-100,000	Gram stain usually positive	Turbid/pus	Aspiration to dryness; may need ultrasound	Systemic symptoms, Gram stain Blood and synovial fluid culture
Gonococcal arthritis	Neutrophils 10,000-100,000	Gram stain usually positive	Turbid/pus	Aspiration to dryness; may need ultrasound	Systemic symptoms, Gram stain Blood and synovial fluid culture
Crystal arthritis	Neutrophils 10,000-100,000	—	Turbid/pus	XR, CPPD	Presence of appropriate crystals Acute serum urate unreliable
Tuberculous arthritis	Mononuclear 5000-50,000	Acid-fast stain often negative	Turbid/pus		At-risk population Ziehl-Neelsen stain biopsy may be necessary
Inflammatory monoarthropathies	Neutrophils 5000-50,000	—	Slightly turbid	Ultrasound/MRI for early synovitis and erosions	Serum autoantibodies such as RF, ACPA, ANA
Osteoarthritis	Mononuclear 0-2000	—	Clear	XR changes	Usually noninflammatory CPPD may be present
Internal derangement	Red blood cells	—	Clear/turbid	MRI	Arthroscopy may be necessary
Trauma	Red blood cells	—	Clear/turbid	XR	Tc bone scan may aid diagnosis if radiograph normal
Ischemic necrosis		—		MRI in early disease	XR abnormal only in advanced cases
Rarer Causes					
Sarcoidosis	Mononuclear 5000-20,000	—		CXR	
PVNS	Red blood cells	—	Turbid	Ultrasound and MRI	Synovial biopsy essential
Charcot's	Mononuclear 0-2000	—		XR	CPPD may be present
Lyme disease	Neutrophils 0-5000	—	Clear/turbid		SF eosinophilia may be found
Amyloid	Mononuclear 2000-10,000	—	Turbid		Serology for <i>Borrelia</i> Synovial biopsy for Congo red stain

ACPA, anticitrullinated protein antibody; ANA, antinuclear antibody; CPPD, calcium pyrophosphate dehydrate deposition; CXR, chest radiograph; MRI, magnetic resonance imaging; PVNS, pigmented villonodular synovitis; RF, rheumatoid factor; SF, synovial fluid; XR, radiograph.

is often required for diagnosis.¹³ Proteomic and genomic assays begin to show differences in the synovium from chronic arthritides, so synovial biopsy use may increase in the future. Bone biopsy may be needed to identify tumors and relevant factors in nonresolving osteomyelitis.

SPECIFIC DIAGNOSES

Acute Monoarthritis

Septic Arthritis (Bacterial)

The presence of bacteria in synovial fluid or after culture is a medical emergency because the acute mortality of septic arthritis is approximately 15%.¹⁴ Large limb joints are most frequently involved,¹⁵ usually associated with underlying osteoarthritis or inflammatory arthropathies, especially RA.^{14,16} Patients are particularly at risk following joint surgery, arthroplasty, or intra-articular injection, as are patients with a distant infection, intravenous drug users,¹⁷ and those with underlying disease or drugs that impair the

immune response.¹⁸ Recent studies have shown that the most deprived in our communities are also at risk.¹⁴

History often elicits an acute, painful, swollen monoarthritis, but it is noteworthy that more than 10% of patients with native joint infections present with polyarticular infection. At presentation, an identifiable distant site of infection may be found, but fever occurs in less than 50% and sweats/rigors occur in approximately 30%.¹⁴ Blood cultures may identify bacteria in patients where synovial fluid culture is negative. At presentation, ESR and CRP are almost invariably raised, but approximately 35% of all septic arthritis patients do not have a raised WCC, and when infection is in the context of underlying RA this figure rises to 50%. Impaired renal and liver function at presentation can predict a poorer outcome.¹⁴

Plain radiographs show soft tissue swelling, and ultrasound localizes synovitis and fluid collection to target aspiration. MRI may demonstrate additional osteomyelitis. Synovial fluid is usually cloudy with a high WCC, and Gram stain should be undertaken.¹ Synovial fluid culture is mandatory, yielding an organism after culture in

approximately 50% of cases—local protocols for antibiotic use should be instigated therefore *before* culture results are available. Organisms detected most commonly include staphylococci (*Staphylococcus aureus* and *Staphylococcus epidermidis*), streptococci, and gram-negative bacteria with an increasing prevalence of methicillin-resistant *S. aureus*.^{12,19} Prompt intervention can reduce mortality^{10,14}; hence the joint must be aspirated to dryness, but this can usually be done without recourse to surgical intervention.²⁰

Interestingly, results from history, examination, routine investigations, and outcome are identical when comparing patients with bacteria-proven septic arthritis with those where a clinical diagnosis of septic arthritis is made but where bacteria cannot be isolated.¹² Hence absence of systemic symptoms and normal investigations should not negate a strong clinical diagnostic suspicion.

Infection with *Neisseria gonorrhoeae* can be asymptomatic but should be suspected in sexually active patients presenting with migratory arthralgias, tenosynovitis, skin rashes, and vesicles. Untreated *Neisseria* infection can also lead to destructive arthritis. Most patients will be febrile with a raised acute phase response and blood WCC, but as with other bacterial causes of septic arthritis these may be normal at presentation.²¹ Investigations should include swabs from the urethra, cervix, pharynx, and rectum, inoculated immediately on Thayer-Martin medium. In contrast with other bacteria, polymerase chain reaction has been used on synovial fluid to improve positive results.²²

Crystal Arthritis

Gout

Podagra is the classic monoarthritis of the first metatarsophalangeal joint, but other lower limb joints can be affected.²³ Patients tend to be obese males, aged 40 to 50 with hypertension, and consumers of excess alcohol.²⁴ Increasingly, postmenopausal females with low estrogens and who take loop diuretics for hypertension are predisposed to gout. Tophi are indicative of the diagnosis.

Fever is present in 34% of patients, especially in polyarticular presentations.²⁵ In acute settings, blood WCC, ESR, and CRP are raised and to this extent gout mimics septic arthritis. Serum uric acid may be raised, but levels are low in 33% during acute attacks.²⁶ Renal and liver function should be assessed. Needle-shaped uric acid crystals (that are negatively birefringent under polarized light) are present in synovial fluid or tophi aspirate and confirm the diagnosis.²⁷ Synovial fluid should be examined for bacteria to exclude concomitant septic arthritis.

Routine radiographs frequently show no bony abnormalities but may identify erosions after repeated or prolonged attacks. Diagnostic ultrasound and MRI can identify synovial fluid for aspiration, tophi, and erosive disease.²⁸

Pseudogout

Patients with pseudogout or pyrophosphate (CPPD) arthropathy present with similar symptoms, usually in the knee or wrist in older females often concurrent with osteoarthritis.²⁹ Acute attacks often occur following a trigger such as infection, trauma, or surgery.³⁰ Calcinosis can be seen in

cartilage, and periarticular tissues can be seen on a radiograph. Ultrasound may assist in the diagnosis of pyrophosphate arthritis because crystal deposits may be observed by careful practitioners.³¹ Synovial fluid microscopy demonstrates rhomboid-shaped crystals at $\times 400$ magnification.³² Culture should exclude coexistent septic arthritis. Hemarthrosis necessitates review for an occult fracture. Repeat imaging (e.g., using MRI) may be necessary to formally exclude bone injury if clinical suspicion exists.

Acute Calcific Periarthritis

Calcium deposition in periarticular tissues is common adjacent to upper and lower limb large joints. Many patients are asymptomatic, but an acute shoulder monoarthropathy with loss of function is well recognized. Calcium crystals can be associated with subacromial bursitis,³³ identified on routine radiographs, ultrasound, or MRI.³⁴ Hypercalcemia necessitates that hyperparathyroidism should be excluded.

Calcium Phosphate Crystal Arthritis

Intra-articular deposits of basic calcium phosphate (BCP) are rare but present in older female patients with osteoarthritis, with a destructive shoulder arthropathy usually on the dominant side (Milwaukee shoulder) as an acute on chronic monoarthritis.³⁵ The effusion is not inflammatory, but synovial fluid can be viscous and blood-stained and may contain calcium aggregates and cartilage fragments. Plain radiographs show upward shoulder dislocation, and MRI exhibits characteristic features and may be useful in differential diagnosis, which should include sepsis.

Cholesterol Crystal Arthritis

Cholesterol crystals have been reported in synovial fluid, albeit rarely and often in association with inflammatory arthropathies. Whether these large rhomboid-shaped crystals are truly a separate cause of synovial inflammation remains a subject for speculation.

Reactive Arthritis

Reactive arthritis characteristically presents as a large joint monoarthritis, a flitting polyarthritis, or enthesitis with a history of preceding throat, urogenital, or gastrointestinal tract infection.³⁶ Patients can present with coexistent circinate balanitis, sterile urethritis, and keratoderma blennorrhagica. Uveitis may precede arthritis and requires urgent review. Urethral cultures should be performed. The findings of an inflammatory synovial fluid with no bacteria after culture and lack of crystals should exclude other acute arthritides. The acute phase response is usually high, and conventional radiologic investigations and ultrasound can identify synovial swelling and effusions, but MRI is particularly useful for identifying enthesitis and extra-articular soft tissue disease.³⁴ The high radiation exposure associated with standard sacroiliac joint radiographs has led to the increased use of MRI to assess for active sacroileitis in patients with coexistent back pain. Autoantibody tests are usually negative, and the link with HLA-B27 may be suggestive but is of limited diagnostic use. Antibodies against *Chlamydia*,

Shigella, *Salmonella*, and *Campylobacter* can be found³⁷ but are often negative.

Lyme Disease

Patients with Lyme disease live in, or travel through, recognized at-risk geographic areas and present with expanding erythematous rashes after a “tick bite” resulting from *Borrelia* infection, usually *Borrelia burgdorferi*. Large joint monoarthritis develops a few weeks after initial infection³⁸ associated with a high ESR and CRP. Specific IgG antibodies, detected 4 weeks after infection, are diagnostic. Low levels of rheumatoid factor and ANAs can be detected. Synovial fluid contains polymorphs, and *Borrelia* organisms may be cultured, but PCR of synovial fluid for *Borrelia* DNA represents a superior test.³⁹

Plant Thorn Synovitis

Foreign bodies including plant thorns cause inflammation in intra-articular and tendon synovial tissue in hands or feet, but history of penetrating injury may be absent. Ultrasound, CT, and MRI are helpful⁴⁰ in localizing foreign bodies, but synovial biopsy can make the diagnosis. Synovial fluid can be sparse but may be infected with *Enterobacter agglomerans*, a gram-negative bacillus commonly found in soil.

Other Organisms Producing Monoarthritis

Monoarthritis resulting from tuberculosis should be considered in at-risk populations and people with a relevant social history. Synovial fluid contains mononuclear cells, but synovial biopsy may be required to identify organisms.

Polyarthralgia after viral infection is common. Rubella, herpes, and hepatitis B and C infections are reported to present as a monoarthritis. Arthropathies occur during infection with and treatment for human immunodeficiency virus. Other features in the presenting history and examination findings can be diagnostically useful.

Arthritis, tenosynovitis, and bone lesions are reported following fungal and parasitic infections, but most infectious lesions are extensions of underlying disease.

A reactive arthritis (Poncet's disease) can occur after tuberculosis infection elsewhere and may also follow viral and fungal infections.

TRAUMA AND INTERNAL DERANGEMENT

Trauma, either acute or after repeated injury, is the commonest cause of acute monoarticular pain, especially in the knee and the ankle. In the knee, torn menisci or loose bodies in the synovial fluid “wedge” between articulating surfaces leading to sudden and painful locking and weakness when walking described as “giving way.” History is diagnostic and examination using REMS can elicit locking using McMurray's test. Examination for other ligament damage is mandatory, using tests for cruciate or collateral knee ligament stability. Careful attention to inversion and eversion stability of the ankle is also essential for monoarticular pain

in that area. Plain radiographs may demonstrate abnormal architecture, dislocation, or loose bodies, but MRI will usually establish the cause of a trauma-related diagnosis. Arthrography may be required to assess the hip for damage, particularly to establish tears in the acetabular labrum.

Stress fractures may be incomplete but cause monoarticular pain on weight bearing and occur after repeated minor trauma (e.g., March metatarsal fracture). Note, however, that stress fractures may occur secondary to underlying local or systemic bone disease, particularly in sedentary individuals and those on prolonged bisphosphonate therapy. These can be missed on standard radiographs, and so CT, MRI, or bone scintigraphy can be helpful in the context of persistent localizing regional articular pain.

Osteonecrosis commonly affects the hip in children (Legg-Calvé-Perthe) but can involve metatarsal heads (Freiberg), humerus, or lunate.⁴¹ Osteonecrosis after neck of femur fracture results from reduced vascular supply. This is also observed in recipients of systemic glucocorticoids and in patients with connective tissues diseases, especially SLE. Other causes of osteonecrosis include decompression sickness, hemoglobinopathies, and hyperlipidemias in alcoholics and patients with hyperuricemia. History is of monoarticular pain, but examination can be normal. Plain radiographs are often normal in early phases of the disease, but early MRI is diagnostic.⁴¹

The presence of acute hemarthrosis suggests trauma, overanticoagulation, or inherited clotting abnormalities. Hemangiomas, lipoma arborescens, and pigmented villonodular synovitis may be suspected in the context of recurrent effusions that are resistant to local interventions such as glucocorticoid injection. Ultrasound and particularly MRI represent the investigations of choice before proceeding to biopsy if these are suspected.

POLYARTHRITIS PRESENTING AS ACUTE MONOARTHRITIS

Patients with a personal or family history of psoriasis may develop monoarthritis,⁴² digital dactylitis, or enthesitis. Radiographs may show proliferative new bone formation along the metacarpal shaft or periarticular erosions in longstanding disease. Ultrasound and MRI can differentiate inflammation at tendon insertions from synovitis⁴³ and can localize synovial fluid that, if aspirated, is usually aseptic and inflammatory in character.

Up to 25% of inflammatory bowel disease patients can present with a seronegative lower limb large-joint acute monoarthritis⁴⁴ often during exacerbation of bowel symptoms. Synovial biopsy from Crohn's disease patients may show granulomas. In Whipple's disease, 60% of patients present with large migratory joint monoarthritis or oligoarthritis.⁴⁵ Blood tests confirm a high acute phase response with leukopenia, whereas synovial fluid usually shows a high WCC. The diagnosis is based on detection of periodic acid-Schiff-positive material (probably from *Tropheryma whippelii*) in jejunal macrophages and in foamy cells on synovial biopsy. There are reports of short-lived peripheral joint oligoarthritis in approximately 25% of patients with celiac disease.⁴⁶ A seronegative erosive arthritis with inflammatory synovial fluid and lymphocytic infiltrate on

biopsy occurs after jejunoileal surgery for obesity,⁴⁷ but arthropathies are not a significant problem after less invasive gastric banding surgery.

Up to 20% of patients presenting with acute knee monoarthritis progress to develop RA.⁴⁸ This is an important diagnosis to make with a high acute phase response, rheumatoid factor, and anticyclic citrullinated protein antibodies being useful markers in early disease. The presence of an intermittent inflammatory monoarthritis lasting a few hours or days associated with a temporary rise in acute phase response suggests palindromic rheumatism. MRI and ultrasound in these patients show synovitis, which may be transient.⁴⁹ Patients with positive rheumatoid factor and anti-CCP antibodies are at high risk of developing RA within 5 years. Many such patients may meet the American College of Rheumatology (ACR)/EULAR/2010 diagnostic classification criteria for RA⁵⁰ and on this basis would merit earlier therapeutic intervention.

In adolescent boys, a monoarthritis may represent the harbinger of spondyloarthropathy. Features of inflammatory back pain, duration of pain for more than 3 months, and presence of HLA-B27 should raise this suspicion and prompt urgent assessment for peripheral and axial inflammatory disease. Most juvenile inflammatory arthritis (JIA) patients with monoarthritis close to the 16-year age cutoff have lower limb arthritis, commonly knee or ankle involvement, and blood and radiologic investigations are similar to those with adult-onset disorders. Uveitis with inflammatory arthritis suggests the ANA-positive variety and requires regular ophthalmologic investigation. Systemic adult-onset JIA is characterized by polyarthritis, a transient salmon pink rash, fever, and serositis. A high serum ferritin and acute phase response is found, and abnormal liver function is common. Synovial fluid shows a high neutrophil leukocytosis.⁵¹

MONOARTHROPATHIES ARISING FROM OTHER JOINT DISEASES

Osteoarthritis presents as a chronic noninflammatory polyarthropathy with a classical joint distribution. A history of intra-articular fracture or recurrent occupational-related injury (carpet fitter's knee) or previous joint surgery (arthroscopy or arthrotomy) can lead to a more localized osteoarthritis.⁵² In younger patients with hip osteoarthritis, slipped epiphysis, congenital dislocation, or avascular necrosis may antedate disease. Blood investigations will usually be normal, and synovial fluid shows a low white cell count. Ultrasound and MRI help clarify the extent of synovitis and fluid collection, as well as guide aspiration, but plain radiographs usually confirm the diagnosis. In the presence of more inflammatory symptoms it is important to exclude crystal deposition and/or infection,¹⁴ but inflammatory osteoarthritis may develop and require additional therapy.

Neuropathic arthropathy (Charcot's joint) should be suspected in patients in whom there is a monoarthritis in the distal lower limb with severe osteoarthritis on radiograph in association with demonstrable peripheral neuropathy. Any peripheral neuropathy can lead to this arthropathy, but the fall in syphilis incidence means that diabetes mellitus is the commonest cause in the Western world.⁵³

The arthropathy secondary to hemochromatosis results from iron accumulation in joint tissues with osteophytes in the second and third fingers with abnormal liver function and iron saturation tests. PCR of the *HFE* gene, which regulates iron transport, often demonstrates sequence variations. The arthropathy associated with alkaptonuria affects the spine and large joint degenerative arthritis seen on radiographs. Discoloration of ear cartilage and sclera is diagnostic.

SYNOVIAL CAUSES OF NONINFLAMMATORY MONOARTICULAR PAIN

Pigmented villonodular synovitis should be suspected in patients with recurrent monoarticular swelling with blood-stained effusions. MRI is the investigation of choice, but synovial biopsy is essential for pathologic confirmation.⁵⁴ Primary or secondary tumors in periarticular tissues including bone can present with single joint pain and are usually diagnosed following routine radiographs or MRI, or both.³⁴

Lipoma arborescens is being more widely recognized as a result of increasing use of MRI in rheumatology.⁵⁵ Patients with this benign tumor, in which synovium is replaced by mature fat cells and villous transformation, usually present with a chronic history of acute knee joint swelling with effusions. MRI changes show villous proliferation of the synovium with characteristic features similar to subcutaneous fat.⁵⁶ Occasionally lipoma arborescens occurs together with other arthropathies such as psoriatic arthritis.⁵⁷

Synovial osteochondromatosis presents with symptoms of pain and locking in the large joints, predominantly hips and knees. Synovial fluid is pale in color with few cells. Plain radiographs show calcification in synovial tissues, and synovial histology after biopsy shows the formation of osteo-cartilaginous bodies in the synovial membrane.⁵⁸

Complex regional pain syndrome type I (reflex sympathetic dystrophy or algodystrophy) usually affects upper limb extremities, often following a triggering event. Pain is diffuse with a burning quality and is worsened after a minor stimulus, and local weakness limits movement. Skin swelling and color change is common with the affected limb being warm. Thermography can identify local increased temperature, bone scintigraphy shows differences between the affected and normal sides, and MRI shows patchy osteoporosis. Synovial fluid contains high protein levels but a low cell count. Hypervascularity and hyperplasia of arteriole walls are seen on synovial biopsy with limited cellular infiltrate or proliferation.⁵⁹

MONOARTICULAR ARTHRITIS IN SYSTEMIC DISEASES

Systemic vasculitides including giant cell arteritis, ANCA-associated vasculitis, Henoch-Schönlein purpura, Behçet's disease, and connective tissue diseases such as Sjögren's syndrome and SLE may present with arthralgia and occasionally oligoarticular synovitis. Relevant symptoms and signs and appropriate investigations should make the diagnosis. Sudden onset of new monoarticular symptoms in

patients with SLE, particularly those on steroids, should raise the possibility of infection or trauma with tendon damage.⁶⁰ In avascular necrosis MRI is the investigation of choice.⁶¹

Sarcoidosis represents approximately 4% of cases in early synovitis clinics being linked with ankle arthritis, erythema nodosum, and bilateral hilar lymphadenopathy.⁶² Patients are seronegative for rheumatoid factor and have a high acute phase response, but hypercalcemia is not common at presentation. ACE levels may be raised in patients with active widespread sarcoidosis but are often negative in acute joint disease.⁶³ Synovial fluid contains lymphocytes, and synovial biopsy shows noncaseating granulomas.⁶⁴ Chronic arthritis is uncommon, but sarcoidosis of bone may present as a dactylitis with bone cysts in the phalanges detected on plain radiograph.³⁴

Amyloid protein deposition (AL or AA) produces an arthropathy with noninflammatory synovial fluid, which is diagnosed on synovial biopsy.⁶⁵ Amyloidosis can be primary (AL) with deposition of light chains in patients with myeloma. Secondary (AA) amyloid is often associated with chronic infectious or inflammatory diseases or rarely of familial etiology. Amyloid secondary to β_2 microglobulin deposition was previously seen after long-term dialysis.

In hereditary periodic fever syndromes, patients, often with a Mediterranean connection, may have acute short-lived episodes of monoarthritis with serositis and high fevers. The acute phase response is high, as might be expected from the neutrophil synovial infiltrate. Many genetic associations in the *HFE* gene now exist across the range of autoinflammatory disorders.⁶⁶

Relapsing polychondritis is an episodic disorder in middle-aged Caucasians that destroys synovial joint cartilage and mimics acute monoarthritis. Ear pinna, nose, larynx, bronchi, and sclera can be affected, as can the aortic valves and aortic root. Synovial fluid is noninflammatory, but the acute phase response is raised, often with a leukocytosis. Biopsy shows an active cellular infiltrate into cartilage, and antibodies can be detected against a variety of cartilage constituents. Repeated episodes lead to local damage and deformity.⁶⁷

REGIONAL DIFFERENTIAL DIAGNOSIS OF MUSCULOSKELETAL PAIN

Injuries to soft tissues present with pain in the region of local joints and hence are often misconstrued as “monoarthritis” by patients. Table 41-4 shows a list of the most frequent causes of soft tissue injury. These conditions are not usually associated with active synovitis in the joint. Blood investigations are usually normal, as are plain radiographic images unless there is local soft tissue swelling, calcification, or underlying joint damage. Ultrasound is the quickest method of imaging to demonstrate local injury to tendons, entheses, or bursae.⁶⁸ MRI is also reliable but costly to perform.³⁴

MONOARTICULAR PAIN RESULTING FROM PERIARTICULAR DISORDERS

Local skin infections can mimic acute synovitis, especially in superficial joints. Deep intra-abdominal infections can

Table 41-4 Common Soft Tissue Disorders That Arise after Local Injury by Region

Upper Limb

Metatarsalgia
Morton's neuroma

cause pressure on femoral and sciatic nerves presenting with hip, knee, or sacroiliac joint pain.⁶⁹ The limited signs can lead to delay in diagnosis with consequent increasing systemic toxicity. Investigations will be similar to those of septic arthritis, but ultrasound, CT scanning, MRI, and nuclear medicine WCC scans should localize the exact site of infection. Neuropathic pain can mimic acute arthropathy. Pain from carpal tunnel syndrome can radiate down the arm to the fingers but equally can produce symptoms in the upper arm. Nerve conduction studies are the investigation of choice before injection or surgery, but ultrasound and MRI can be used to identify pressure on the median nerve. Pressure on the lumbar (and cervical) nerve roots can cause pain radiating into the affected limb and can localize into single joints. MRI of the spine is the investigation of choice to examine for disk protrusion or other local pathology. Blood investigations are usually normal.

Patients with chronic pain syndromes have poorly localized widespread pain often with headaches, irritable bowel syndrome, fatigue, and multiple pressure point tenderness. Symptoms can start from localized pain in a single area, which may be close to joints and hence mimic monoarthritis. Multiple trigger points are found on examination, but

serum, radiologic investigations including MRI, bone scintigraphy, and ultrasound are normal.

Bone pain presenting as acute monoarticular pain is frequently an undiagnosed fracture or resulting from metastatic disease but may be an osteoid osteoma, Paget's disease, or osteomyelitis. Acute bone pain may be indicative of osteosarcoma when associated with a limp in adolescents. Imaging investigations may require technetium bone scans or MRI if standard radiograph is not helpful.

KEY POINTS

Polyarthritis is pain of synovial or articular origin, with or without inflammation, in four or more joints.

The history and physical examination are essential elements for diagnosis.

Exclude fibromyalgia as a cause of pain, and evaluate for common causes such as osteoarthritis.

Identify patients who are likely to have persistent, destructive disease.

Initiate prompt therapy in those with poor prognostic indicators.

Articular disorders are the most common cause of disability in the United States. Recent estimates by the Centers for Disease Control and Prevention (CDC) reveal that approximately one in five (49.9 million) adults in the United States have reported doctor-diagnosed arthritis; of these, 21.1 million adults have reported arthritis-attributable activity limitation.¹ A substantial number of these patients manifest polyarticular joint involvement. The presentation of polyarticular joint pain poses a diagnostic challenge to the clinician, given the magnitude of the complaint, urgency to provide relief and preserve joint function, and the uncertainty of the outcome. Although many articular complaints (e.g., tendinitis, bursitis) are self-limiting and require only time and symptomatic management, others may present with or persist as chronic polyarthritis, with the potential for joint damage or disability. Knowledge of the most prevalent or commonly misconstrued causes of polyarthritis can facilitate an accurate diagnosis and appropriate therapy. This chapter will examine the diagnostic approach to polyarthritis, leaving its management to relevant chapters found throughout this textbook (see Chapters 71, 75 through 78, and 81).

EPIDEMIOLOGY AND SOCIETAL IMPACT

The prevalence of arthritis is expected to rise as the U.S. population ages; an estimated 60% of the U.S. population older than 65 is affected by chronic joint symptoms.² In 2002, the Behavior Risk Factor Surveillance System (BRFSS), a state-based random digit-dialed telephone survey of the U.S. civilian population, found that 69.9 million Americans had chronic joint symptoms defined as pain, aching, or stiffness in or around the joints lasting longer than 3 months.³ Of these, 25.1 million had not seen a physician, and more than 2 million had activity limitations. The survey also found that those who had never seen

Polyarticular Arthritis

JOHN J. CUSH • KATHRYN H. DAO

a health care provider for their joint complaints were likely to be male, to have lower educational levels, and to have no health insurance.⁴ An estimated 25% of patients will be unable to work within 7 years of disease onset. Direct and indirect costs are estimated at 1.2% of the U.S. gross domestic product, or \$128 billion.^{1,5} These statistics encompass all forms of arthritis and extol the pervasive societal impact and cost of arthritis and the diagnostic deficit that exists. Thus a facile and accurate approach to patients with joint symptoms is sorely needed.

DEFINING POLYARTHRITIS

Polyarthritis is classically defined as pain (with or without signs of inflammation) that affects four or more joints. In the pediatric literature, polyarthritis applies to those with involvement of five or more joints. The distinction between these definitions is moot in that both definitions imply a significant risk of added joint involvement over time. Hence, without an early diagnosis and appropriate management, polyarthritis begets polyarthritis. Patients with chronic involvement of one (monoarthritis) or two or three joints (oligoarthritis) are at low risk of polyarthritis, even with the passage of time.

The differential diagnoses underlying polyarticular complaints can be extensive and intimidating to the inexperienced. Narrowing these to firm a diagnosis is best accomplished in four diagnostic steps:

1. Evaluate for the most prevalent causes—trauma, osteoarthritis, and fibromyalgia.
2. Distinguish between acute and chronic polyarthritis.
3. Delineate articular from periarticular disorders.
4. Elicit clues to increase the likelihood of a diagnosis.

Although many rheumatologists advocate a chronologic (acute vs. chronic), pathophysiologic (inflammatory vs. noninflammatory), or anatomic (oligoarticular vs. polyarticular, periarticular vs. articular) approach to diagnosis, such an approach yields insight into underlying processes without focusing on the most likely conditions, thereby leaving the examiner with a wide range of possibilities. For example, the differential diagnosis of a chronic inflammatory polyarthritis may include rheumatoid arthritis (RA), undifferentiated polyarthritis, psoriatic arthritis, juvenile idiopathic arthritis (JIA), viral arthritis, serum sickness, and tophaceous gout and pseudogout, to name just a few. Regardless of the preferred approach, the diagnosis of polyarthritis relies heavily on an intelligent and accurate history and examination. Hence, key factors such as onset of acuity, course of disease progression, and evidence of inflammation are more diagnostic than a battery of poorly chosen laboratory investigations. Early diagnosis and treatment is the

primary goal, particularly when inflammation is present, in which case earlier treatment can avert considerable disease-related morbidity.

APPROACH TO DIAGNOSIS

Frequent Noninflammatory Polyarticular Scenarios

It is crucial that the clinician consider the most common causes of polyarticular and widespread musculoskeletal complaints—osteoarthritis (OA) and fibromyalgia (FM). Osteoarthritis affects 12 to 27 million, and fibromyalgia and related disorders (chronic fatigue syndrome, chronic widespread pain) affects 5 to 11 million in the United States alone.¹ Although these two conditions are easily distinguishable from other arthropathies on clinical grounds (without laboratory or radiographic investigation), they often are missed for several reasons. First, it is possible to have more than one condition; RA is frequently accompanied by some degree of degenerative arthritis that may be constitutive, posttraumatic, or secondary to antecedent inflammatory disease. Similarly, patients with systemic lupus erythematosus (SLE) or Sjögren's syndrome may have secondary FM observed as uncontrolled pain and poor sleep. Second, patients who once had an arthropathy (e.g., an inflammatory arthritis such as psoriatic arthritis) may find that it evolves into another type of arthritis. For example, psoriatic arthritis may cause years of swelling, stiffness, inflammation, and joint damage, only to “burn out” years later. However, the pattern of pain and stiffness may persist owing to secondary OA or FM, even though evidence of inflammatory arthritis is limited or nonexistent. Last, a detailed and skillfully performed musculoskeletal examination is required to discern that the joint pain is articular (e.g., RA) rather than extra-articular (e.g., FM) in origin, or that the swelling is related to synovial (e.g., RA) rather than bony (e.g., OA) hypertrophy, or that widespread pain is accompanied by tender trigger points (e.g., FM) rather than enthesitis (e.g., ankylosing spondylitis).

Fibromyalgia

This condition is five times more prevalent than rheumatoid arthritis and may underlie 10% to 20% of all outpatient musculoskeletal visits.² It affects women more so than men, usually between the ages of 30 and 60 years, but people of all ages can be affected. Few patients announce widespread pain and tender points at presentation. Instead, most present because of regional joint or muscle pain, profound fatigue, and problems with mentation, memory, or headaches. Only upon further questioning will the examiner discern the wider distribution of painful tender points, joints, muscles, and tendons with an associated recent or long history of poor sleep. FM is a pain amplification disorder, with lowered pain thresholds, that often is accompanied by other “spastic conditions,” including migraine, irritable bowel syndrome, primary dysmenorrhea, atypical chest pain (often mislabeled as costochondritis), temporomandibular joint pain (without dysfunction or damage), and low back or neck pain. Diagnostic testing (laboratory tests, radiographs) is

not necessary. The syndrome is established by history and examination and can be confirmed by (1) a positive response to simple analgesics, (2) improved sleep with better sleep hygiene plus sleep aids, (3) improvement attained with a stretching exercise program (e.g., swimming, Pilates, yoga, tai chi, physical therapy), and (4) uncontrolled depression or anxiety.

Osteoarthritis

Although nearly 27 million patients in the United States have radiographic evidence of articular degeneration, less than half clinically manifest symptoms of OA. It is important to note that although pain should be accompanied by radiographic OA findings, the extent of radiographic findings and the clinical symptoms reported are often quite discordant. Osteoarthritis should be suspected in patients older than 60 years of age, in those with a history of trauma, and in those whose pain is accentuated by activity. Physical examination may disclose bony hypertrophy (e.g., Heberden's nodes), joint crepitus, or limited range of motion.

OA and FM can be considered or excluded on the basis of clinical findings. Should these not be applicable, other, more common disorders may be considered according to the chronology of the complaint (acute vs. chronic), the age of the subject, the presence of inflammatory or noninflammatory symptoms, and clues indicating high specificity (Figure 42-1).

History

The diagnosis of any polyarticular process relies heavily on the history and physical examination. When faced with a patient who presents with joint complaints, the goal of the encounter is to have answered the questions, “Is joint inflammation present?” and “Will it remit or persist?” This is important because inflammation that persists may yield significant damage or disability. In addition, it is estimated that more than half of patients who present with acute undifferentiated (often seronegative) polyarthritis will spontaneously remit. Although a 6-week history demarcates acute from chronic arthritis, persistent/chronic polyarthritis is best predicted by articular symptoms lasting 12 weeks or longer. Figure 42-1 presents an algorithm that may assist in formulating a differential diagnosis by providing answers to these questions. The algorithm considers patient demographics, symptom onset, patterns of involvement, disease course, and presence or absence of inflammation.

Demographics. Age, sex, and family background may provide clues to the type of arthritis. Gout is more common in men than in women; osteoarthritis affects older patients more often than younger counterparts, and spondyloarthritis have greater familial association than is seen with other inflammatory arthritides. Table 42-1 lists the differential diagnoses of patients who present with inflammatory arthritis according to age and sex.

Symptom Onset. Attention should be paid to how symptoms first began and under what circumstances. Eliciting a history of disease onset may be difficult if patients suffered from their illness for years, but identifying the

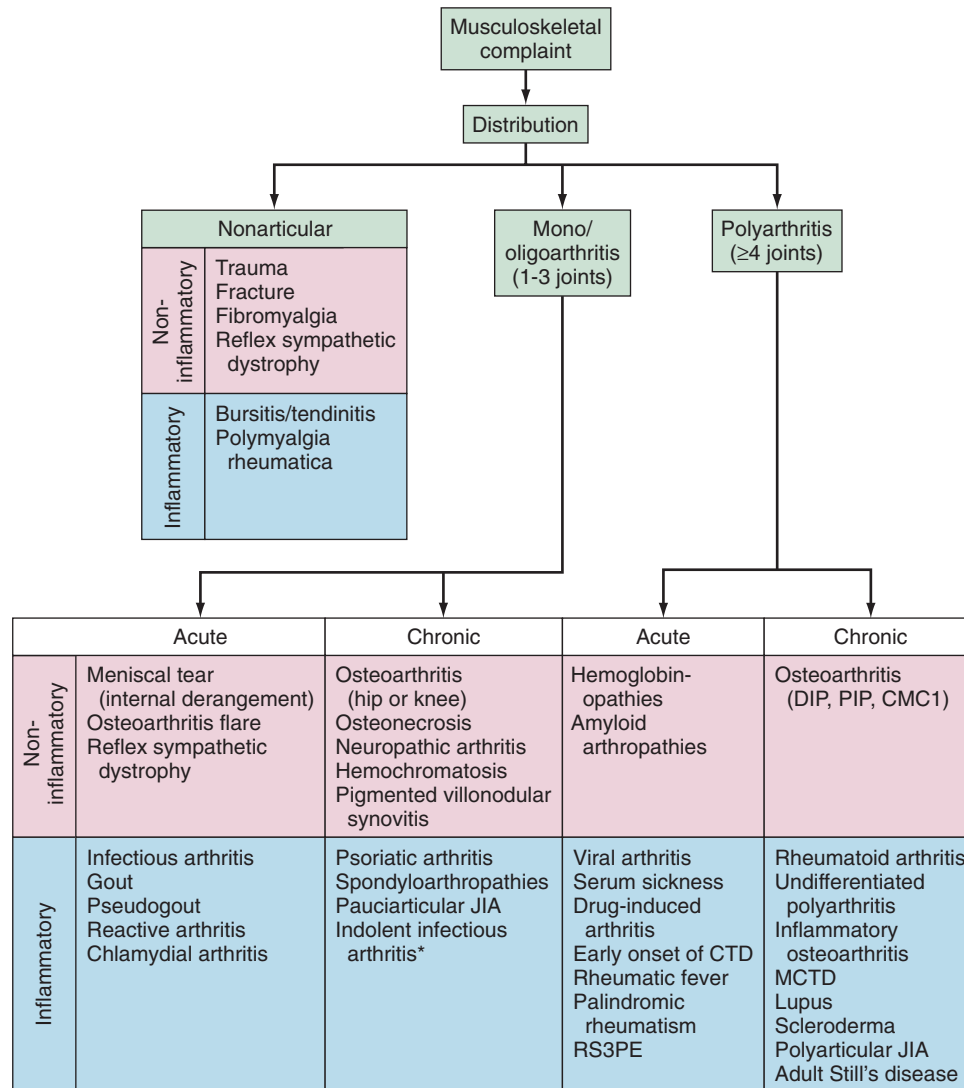

Figure 42-1 Algorithm for assessing initial history and examination. CMC, carpometacarpal; CTD, connective tissue disease; DIP, distal interphalangeal; JIA, juvenile idiopathic arthritis; MCTD, mixed connective tissue disease; PIP, proximal interphalangeal.

acuity of symptoms may aid in diagnosis. If patients present with abrupt onset of symptoms, occurring in a matter of hours/days, the clinician may consider infection, gout, pseudogout, or trauma, whereas if symptoms were present for months/years, rheumatoid arthritis (RA), psoriatic arthritis (PsA), chronic infection (e.g., syphilis, hepatitis, human immunodeficiency virus [HIV]), FM, and OA are among the top differential diagnoses.

Pattern of Joint Involvement. Types of affected joints are often good clues to uncovering the type of arthritis. Consider patients who present with involvement of distal interphalangeal joints (DIPs); this may indicate osteoarthritis or psoriatic arthritis. Contrast these patients with those who have symptoms in their proximal interphalangeal joints (PIPs) and metacarpophalangeal joints (MCPs), where rheumatoid arthritis commonly manifests. Involvement of large joints such as hips and shoulders may suggest polymyalgia rheumatica or a spondyloarthritis.

Disease Course. Noting how the disease progresses may assist in predicting outcome. Patients who have chronic symptoms may describe varying patterns of presentation ranging from an *intermittent pattern*, where attacks are punctuated by periods of complete remission, to an *additive pattern*, where symptoms begin with a few joints and progress to involve more joints with time, or a *migratory pattern*, where certain joints are affected for a time, then the disease remits, only to reappear elsewhere in other joints.

Presence of Inflammation. Evaluation for inflammation may be difficult. Studies have examined features of the history that may provide diagnostic clues to inflammation, such as morning stiffness and response to activity. Clearly, patients with all or some of the cardinal signs of inflammation (redness, warmth, swelling, pain in the morning) may have an inflammatory arthropathy. Morning stiffness (an inflammatory finding) is often confused with the “gel” phenomenon (a degenerative feature). Morning stiffness,

*Spondyloarthropathies include ankylosing spondylitis, psoriatic arthritis, reactive arthritis, and enteropathic arthritis.

†Infectious arthritis includes gonococcal arthritis, Lyme arthritis, viral arthritis, and bacterial arthritis.

‡Connective tissue disorders include systemic lupus erythematosus, scleroderma, Behçet's disease, mixed connective tissue disease, and polymyositis/dermatomyositis.

§Vasculitis includes polyarteritis nodosa, granulomatosis with polyangiitis (formerly Wegener's granulomatosis), hypersensitivity vasculitis, and temporal arteritis.

PMR, polymyalgia rheumatica; RA, rheumatoid arthritis; RS3PE, relapsing symmetric seronegative synovitis with pitting edema.

Modified from Lipsky P: Algorithms for the diagnosis and management of musculoskeletal complaints, *Am J Med* 103:62S, 1997.

defined as the time to maximal improvement after an extended period of inactivity (an overnight rest), typically improves with movement.⁶ In patients with inflammatory arthritis, the duration of morning stiffness is typically greater than 60 minutes. The *gel phenomenon* refers to short-lived stiffness that is brought on by short periods of rest and is common to patients with degenerative arthritis. Patients with inflammatory arthritis may present with pain without swelling, swelling without pain, or difficulty performing their activities of daily living without pain or swelling. It is important to distinguish whether inflammation is truly present as the cause of symptoms. Both arthralgia (joint pain) and arthritis (joint swelling from synovial fluid or tissue) may be present in new-onset polyarthritis; hence the joint examination is an essential component in establishing the diagnosis.

Physical Examination

Arthralgia vs. Arthritis. Characteristics that distinguish synovitis include warmth, erythema, tenderness to

palpation, and synovial effusion. Any or all of these findings may accompany arthralgia. Range of motion, muscle strength, and function may be limited around the inflamed joint. In an effort to reduce joint volume and pain, the patient often will involuntarily hold the joint in a position of partial flexion. Hence, joint contractures may indicate an underlying inflammatory process (present or past). In RA, any diarthrodial joint can be affected, but the pattern of involvement typically involves the MCPs, PIPs, wrist, metatarsophalangeal joints (MTPs), and ankle joints.⁶ This pattern of involvement should be distinguished from osteoarthritis (DIPs, PIPs, carpometacarpal [CMC]1, knee, hip, spine), psoriatic arthritis (DIPs, PIPs, wrist, toes), and pseudogout (knee, wrist, MTPs). The accuracy of identifying synovitis depends on the skills and experience of the physician. The reproducibility of the physical examination in identifying synovitis has been a subject of concern raised in several studies.⁷⁻¹¹ One study looked at whether rheumatologists can agree on the diagnosis of inflammatory arthritis; 24 patients were assessed by 6 rheumatologists—complete agreement was found in only 70% of cases; disagreement in the remaining 30% of cases ranged from 1 to 4 rheumatologists recognizing synovitis when others did not.¹²

This is further illustrated by imaging studies. When the physical examination is compared with imaging, the joint examination has a reported sensitivity of 43%, specificity of 89%, and accuracy of 71% with magnetic resonance imaging (MRI) as the reference.¹¹ Given the difficulty for many practitioners of discerning synovitis, Emery and colleagues have advocated the value of the MCP or MTP “squeeze test” (Figure 42-2). Their study found that pain upon transverse compression of the MCP or MTP joints (a positive squeeze test) has better specificity in identifying persistent arthritis than in finding arthritis in three or more joints, or symmetric arthritis.¹³ Currently, the joint examination is the gold standard for detection of synovitis; however, MRI and ultrasound may provide additional diagnostic evidence of synovitis in patients with chronic synovitis that is not evident on joint examination.

Articular vs. Periarticular. Equally important to identifying inflammation is distinguishing articular from periarticular involvement. In patients with articular pain, the joint capsule is diffusely involved; thus, pain is often deep and is associated with a global decreased range of active and passive motion in all planes. Those who have periarticular abnormalities may have point tenderness in the surrounding soft tissue, and pain occurs only with active range of motion in a few planes. The differential diagnoses in patients with periarticular pain may include FM, fracture, bursitis, tendinitis, enthesitis, carpal tunnel syndrome, sickle cell crisis, polymyalgia rheumatica, neuropathy, and Raynaud's phenomenon.

Extra-articular Manifestations. Although joint symptoms are the primary focus of patients who present with pain, extra-articular manifestations may provide clues to the correct diagnosis. Extra-articular manifestations of RA (e.g., nodules, keratoconjunctivitis sicca) are seldom present early in the disease. This sharply contrasts with other forms of polyarthritis wherein extra-articular manifestations are prominent early and may precede the onset of synovitis. This is particularly so with SLE (malar rash, serositis),

Figure 42-2 The metacarpophalangeal compression test.

reactive arthritis (urethritis, conjunctivitis), psoriatic arthritis (psoriasis, nail pitting), and sarcoidosis (lung, fever, uveitis, parotitis). Nodules in the seronegative patient are more likely to be tophi from gout than nodules from RA, because the latter are seen only in those with high-titer rheumatic factor (RF) or cyclic citrullinated protein (CCP) antibodies.

LABORATORY TESTS AND RADIOLOGIC STUDIES

The diagnosis of polyarthritis is made clinically with the history and physical examination; nevertheless, laboratory tests and radiographic imaging may aid in diagnosis, guide treatment, and predict outcome. Laboratory investigation of polyarthritis is indicated with chronicity (symptoms longer than 6 weeks), failure to respond to initial therapy, and the presence of systemic (e.g., fever, rash) or neurologic symptoms.

Laboratory Tests

Acute Phase Reactants

Elevations in acute phase reactants such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) provide a surrogate measure of inflammation; both ESR and CRP have been correlated with poor prognosis and worse radiologic outcomes.^{14,16} However, they do not discriminate well between RA and other inflammatory and noninflammatory arthritides.^{14,17} Not all patients with inflammatory polyarthritis will have elevated ESR or CRP at presentation; some may have elevations in other acute phase reactants such as ferritin, haptoglobin, ceruloplasmin, and complement levels. Other markers of inflammation may include an

anemia of chronic disease and elevated platelets and white cell count.

Serologies

Autoantibodies have been used to guide the classification of various autoimmune diseases. Their performance has been studied for diagnostic and prognostic value.^{18,19} Testing for serologic markers may add significant diagnostic and prognostic value to the evaluation of inflammatory polyarthritis; however, issues of cost, availability, and standardization may not allow for routine use. One of the most commonly ordered tests is the rheumatoid factor (RF). Serum RF is an autoantibody (typically immunoglobulin [Ig]M) that binds to the Fc component of IgG and may play a role in acute inflammatory arthritis. The RF is not required for the initiation of inflammation because patients with agammaglobulinemia have been described to have rheumatoid-like synovitis²⁰⁻²²; indeed, approximately 20% of patients meeting American College of Rheumatology (ACR) classification criteria for RA are seronegative. The rheumatoid factor performs poorly in diagnosing early RA as reported in several studies: in patients with symptoms of less than 1 year, the sensitivity of serum RF ranges from 17% to 59%, and numbers are even lower in patients with symptoms lasting less than 12 weeks.^{14,23-28} The specificity of the rheumatoid factor for RA is also poor in that it may be present in other diseases as well, including viral hepatitis, systemic lupus erythematosus, cryoglobulinemia, Sjögren's syndrome, paraproteinemias, bacterial endocarditis, mycobacterial diseases, syphilis, leprosy, chronic interstitial lung diseases, parasitic infections, and lymphoproliferative malignancies. These conditions may also present with synovitis and may be mistaken for RA. Screening of the population with the RF test generally yields a positive rate of 4% to 5%; hence random use of RF would likely generate more

false-positives than true-positives. The presence of the RF has been found to be predictive of persistent disease and progression with radiologic damage in patients with inflammatory arthritis.^{27,29} Visser and associates noted that a positive IgM RF confers a relative risk of 2.99 for erosive disease; Tunn and Bacon found that RA latex positivity combined with an ESR >30 mm/hr carries a relative risk of 4.33 for persistent synovitis, with a specificity of 94%.^{14,29} Thus, despite the poor performance of the RF in diagnosing RA, it may be useful in predicting aggressive, tenacious disease.

Other serologic markers that have been evaluated for use in early diagnosis of RA include the anticitrullinated protein antibodies (ACPAs or CCP Ab), which are nearly as sensitive as RF but are far more specific for RA. If the CCP Ab test is combined with the RF, one can expect a sensitivity of 58% with a specificity of 100%; positive and negative predictive values are 100% and 88%, respectively.³⁰

The clinical utility of antinuclear antibodies (ANAs) has also been evaluated in patients with polyarthritis. The ANA is not uniquely linked to lupus but may be found in a wide variety of conditions and in normal people, often at low titers; hence the practice of ordering batteries of autoantibodies to make a laboratory diagnosis of arthritis should be avoided. Many of these antinuclear antibodies are found in up to 15% of the normal healthy or elderly population and have low specificity and poor predictive value.⁸ The most common cause for rheumatologic consultation is to explain a low-titer ANA result that has no associated features of lupus. ANAs are a class of autoantibodies that react with various components of the cell nucleus; they may be found in a variety of autoimmune conditions, as well as in healthy individuals. The specificity of this test is poor because ANAs may be found in patients with systemic lupus erythematosus, systemic sclerosis, chronic liver disease, chronic interstitial lung disease, drug-induced lupus, or Hashimoto's thyroiditis. Their prevalence in patients with inflammatory polyarthritis has been well studied. The presence of ANAs in patients with early inflammatory arthritis ranges from 40% to 69%.¹⁹⁻²¹ Titers are generally lower in patients with RA than in those with SLE or systemic sclerosis (SSc). No correlation has been found between ANA positivity and joint inflammation, severity of joint destruction, or persistence of disease. In juvenile idiopathic arthritis (JIA), ANA positivity is modestly correlated with risk of uveitis in the pauciarticular subset of JIA (see Chapter 106).

Genetic Markers

The study of genes has provided insight into many diseases. Associations have been observed between regions of the major histocompatibility complex (MHC) on chromosome 6 and rheumatic diseases. One of the most striking associations is the one between HLA-B27 and the seronegative spondyloarthritides. The gene can be found in approximately 8% of the general population, but the prevalence of HLA-B27 positivity is 90% to 95% in white patients with ankylosing spondylitis (AS).³¹ Table 42-2 lists the frequency of HLA-B27 in the different seronegative spondyloarthritides. Given the low predictive value of the test (0.95% to 9.5%), HLA-B27 should be ordered only when suspicion for spondyloarthritis is moderate.

Table 42-2 Frequency of HLA-B27 Gene in Patients with Seronegative Spondyloarthritis

Disease	HLA-B27 Frequency (%)
Ankylosing spondylitis	95
Undifferentiated spondyloarthropathy	70
Reactive arthritis	40-80
Irritable bowel disease-associated spondyloarthritis	35-75
Psoriatic spondyloarthritis	40-50
Psoriatic peripheral disease	25
Iritis	50
Cardiac conduction defects	80

Adapted from McMichael A, Bowness P: HLA-B27: natural function and pathogenic role in spondyloarthritis, *Arthritis Res* 4(Suppl 3):S153-S158, 2002.

Another gene that has been studied and may aid with diagnosis is the *HFE* gene found in patients with hereditary hemochromatosis (HHC). HHC is an autosomal recessive disorder of iron metabolism; joint pain is the most common complaint of patients who suffer from the disease.³² *HFE* gene mutations are fairly common, and heterozygosity occurs in 1 of 10 white persons; the frequency of homozygotes is around 4.4 per 1000.³² Screening of the general population for HHC is not recommended, but some have advocated targeted screening in patients with suggestive symptoms and laboratory results (e.g., abnormal serum ferritin, transferrin saturation, serum aspartate, or alanine aminotransferase).

Currently, much research is being conducted to identify genetic susceptibility foci that may aid in diagnosis, predict prognosis, and guide therapy in diseases such as SLE, rheumatoid arthritis, gout, osteoarthritis, sarcoidosis, and other rheumatic diseases.

Synovial Fluid Analysis

In patients with oligoarthritis or in those who present with joint effusions, arthrocentesis may be useful in diagnosing patients and relieving symptoms. Synovial fluid from an inflamed joint is typically yellow and turbulent from inflammatory cells. White cell counts are typically greater than 10,000 cells/mm (range, 5000 to 50,000 cells/mm), with a predominance in neutrophils.³³ Evaluation for infection or crystalline arthritis is an important part of the initial assessment of inflammatory arthritis. Once synovial fluid has been aspirated, prompt evaluation under polarized microscopy will maximize the yield for identifying crystals. Joint aspiration is also therapeutic in patients, reducing the pressure imposed on the joint capsule and prolonging the benefits of intra-articular steroids. One study found that aspiration of synovial fluid before intra-articular corticosteroid injections reduces the risk for relapse (23% in the arthrocentesis group vs. 47% in the nonarthrocentesis group; $p = 0.001$) and extends the duration of steroid effectiveness.³⁴ In addition, joint injections may serve as a prognostic indicator. Green and colleagues found that patients whose synovitis persisted 2 weeks after intra-articular corticosteroid placement were more likely to have persistent synovitis after 1 year.³⁵

Anti-CCP Ab, antibody to cyclic citrullinated protein; HAQ, Health Assessment Questionnaire; RF, rheumatoid factor.

Imaging

Radiographic changes may occur early in any polyarticular disease, but detecting these changes by conventional x-rays may be difficult. Often such images are normal or show only evidence of soft tissue swelling. Indications for radiography include (1) history of trauma or injury (to exclude fracture), (2) persistence of joint pain and swelling longer than 6 weeks, (3) suspicion of septic or gouty arthritis, and (4) as a baseline evaluation for a newly diagnosed polyarticular condition. Characteristic findings on radiographs of inflammatory arthritis may include soft tissue swelling, chondrocalcinosis, joint effusion, juxta-articular osteopenia, symmetric loss of articular cartilage with joint space narrowing, and bony erosions. Identification of these abnormalities is important in that radiographic damage has been shown to correlate with loss of productivity and increased functional disability in RA.³⁶ Erosions are important markers of progressive damage. The advantages of x-rays have been proven as they have been shown to help establish prognosis and assess joint damage longitudinally in patients with RA or inflammatory arthritis. In a prospective study evaluating 113 patients for the development of radiographic changes in the first 5 years of rheumatoid arthritis, 26% of patients were found to have signs of damage at the initial visit (mean duration of symptoms, 9.4 months); the rate of radiographic progression was most rapid during the first 2 years but then decreased significantly in the third to the fourth year ($p < 0.01$). Only 11% of patients had no erosions by the end of the study. Erosions often start in the feet and in 14% to 18% remain only in the feet.³⁷ Thus ordering x-rays of the feet is an important part of the initial evaluation, even if patients do not have symptoms in their lower extremities. Radiographic progression is the single most important outcome when assessed by clinical trials because it indicates persistence of inflammation.^{15,16,27}

Other imaging modalities currently being investigated in early arthritis include magnetic resonance imaging (MRI) and ultrasound (US); both have proved sensitive for the

detection of synovitis when clinical examination and conventional radiographs have failed.³⁸⁻⁴⁰ Advantages of these devices include ability to detect subtle synovitis and soft tissue abnormalities as tendon rupture or tenosynovitis and to permit more accurate placement of the needle in diagnostic arthrocentesis and therapeutic injections. Before these tests are ordered, their potential benefits should be weighed against their limitations involving long examination times, availability of equipment, costs, and skills of the observer in interpreting changes.

The eventual diagnosis of polyarthritis will depend on key historic features, a detailed joint examination, and, occasionally, laboratory findings. Most cases can be diagnosed on the basis of clinical grounds, after consideration of the chronology of symptoms (onset, evolution, pattern of joint involvement), background history, and physical findings. Table 42-3 and Figure 42-3 provide helpful tools in the evaluation of patients who present with inflammatory polyarthritis. Reliance on laboratory testing to establish a diagnosis is ill advised because such tests are poorly predictive when used indiscriminately or as part of broad batteries of “arthritis screening” tests. The strength of laboratory and serologic testing is greatly enhanced when they are used to confirm a reasonably strong clinical suspicion garnered by evaluating the history and examination.

UNIQUE SITUATIONS

Undifferentiated Inflammatory Arthritis

Because of the inadequacies of the 1987 ACR RA Classification Criteria for those with early disease, patients with inflammatory polyarthritis are often given the label *undifferentiated polyarthritis*.^{23,25} These older criteria reflected the presence of features that often require time and severity (e.g., symptoms lasting longer than 6 weeks, erosions, nodules, RF positivity), thereby limiting their diagnostic value in new-onset polyarthritis. The newer 2010 ACR/European League Against Rheumatism (EULAR)

Table 42-3 Distinguishing Different Causes of Polyarthritis

Arthritis	Patient Profile	History/Onset	Joints Involved	Type of Arthritis	Supportive Tests
GC	F > M, young, active sexually	Fever, acute oligoarthritis or polyarthritis	Wrist, knee, tenosynovitis	Inflammatory	↑ESR/CRP, ↑WBC
Gout	Men, postmenopausal women	Intermittent oligoarticular early, polyarticular later	MTP, toes, ankle, knee (hands late)	Acute sudden onset, severe pain with attacks	↑CRP, ↑WBC, Normal uric acid in 40% acutely
HHC	M > F, mean age, 50	Intermittent, oligoarticular or polyarticular	MCP, hip, knee, feet	Intermittent or chronic inflammatory	↑ESR/CRP, ↑LFTs, <i>HFE</i> gene, x-rays—chondrocalcinosis and osteophytosis
OA	F > M, ↑Age men w/ knee or hip	Additive oligoarticular or polyarticular	DIP, PIP, first CMC1, knee, hip, MTP, spine	Noninflammatory asymmetric or symmetric, bony swelling	Normal laboratory results
PMR	M = F, older white	Prolonged AM stiffness or soreness, weight loss	Girdle (hip, shoulder) muscles; seldom synovitis	Inflammatory, chronic	Anemia, ↑ESR/CRP, ↑LFTs
PsA	Long history of psoriasis	Insidious, additive	DIP, PIP, knees, feet, spine	Inflammatory, asymmetric oligoarticular	↑CRP/ESR, negative RF, HLA-B27
Pseudogout	M = F, older patients	Intermittent oligoarticular or polyarticular	Knee, wrist, finger, MTP	Intermittent or chronic inflammatory	↑Uric acid ↑CRP, ↑WBC
RA	F > M, 35-50 yr	Insidious, additive	PIP, MCP, wrist, MTP, knee, ankle	Symmetric, inflammatory	↑CRP/ESR, +RF, +CCP
UPA	F > M	Insidious, one to four joints	Same as RA	Inflammatory	↑CRP/ESR
Viral (HBV, HCV)	Hepatitis risk factors	Acute, additive polyarthritis	PIP, MCP, wrist, knee, ankle	Inflammatory	↑ESR/CRP, ↑LFTs, +HCV/HBV serologies

CCP, cyclic citrullinated protein; CMC, carpometacarpal; CRP, C-reactive protein; DIP, distal interphalangeal; ESR, erythrocyte sedimentation rate; GC, gonococcal arthritis; HBV, hepatitis B virus; HCV, hepatitis C virus; HHC, hereditary hemochromatosis; LFT, liver function test; MCP, metacarpophalangeal; MTP, metatarsophalangeal; OA, osteoarthritis; PIP, proximal interphalangeal; PMR, polymyalgia rheumatica; PsA, psoriatic arthritis; RA, rheumatoid arthritis; RF, rheumatoid factor; UPA, undifferentiated polyarthritis; WBC, white blood cell.

RA Classification Criteria were designed with the goal of identifying patients with undifferentiated inflammatory synovitis who are at risk for persistent and/or erosive disease, and who would benefit most from initiation of early effective intervention (see Chapter 70). These new criteria improve the ability to classify more patients with RA; however, the prevalence of certain musculoskeletal disorders should still be considered in evaluating patients with polyarthritis. High-prevalence diseases (e.g., RA, reactive arthritis, gout, pseudogout, spondyloarthropathy, polymyalgia rheumatica, infectious arthritis) should be considered before those that rarely present as polyarthritis (e.g., amyloidosis, sarcoidosis, lymphoma, RS3PE [remitting seronegative symmetric synovitis with pitting edema], vasculitis). Only a minority of patients with early polyarthritis will have RA.

In a prospective study of 233 patients followed for a year (median symptom duration, 31 days), 22% of patients were diagnosed with RA, 32% had unclassified arthritis, and 46% had other diagnoses such as crystalline arthritis, sarcoidosis, reactive arthritis, and psoriatic arthritis.⁴¹ When the study was extended to include a total of 566 patients followed over 2 years (median symptom duration, 2.7 months), results did not change: 30% were diagnosed with RA and 26% with undifferentiated polyarthritis (UPA), and 46% were given another diagnosis.¹⁴ Other early arthritis clinics followed their patients with early undifferentiated polyarthritis and found that up to 65% had remission of symptoms

at 1 to 2 years.^{29,42-44} The prognosis and chance for remission appeared better in this undifferentiated group, which often is more easily managed. Nevertheless, patients with undifferentiated polyarthritis may develop persistent and aggressive disease. Such patients need to be serially evaluated and treatments tailored to complement the aggressiveness of their arthritis. With chronicity comes the need to aggressively treat the patient for RA or undifferentiated polyarthritis—even when serologies are negative.

The Hospitalized Patient

The CDC, in a report derived from hospitalization data of the 1997 National Hospital Discharge Survey, stated that an estimated 744,000 (3%) hospitalizations occurred with arthritis as the principal diagnosis. The most common diagnosis was related to osteoarthritis, followed by soft tissue disorders, spondylosis/spondylitis, and other rheumatic conditions such as infection.⁴⁵ Gout and myalgia, including FM, each account for about 1% of hospitalizations.⁴⁵ How arthritis played a role in hospitalization was not specified, but the authors were clear to point out that hospitalization courses were complicated by the high rates of pain and limitation associated with arthritis.⁴⁵ A U.K. study published in 1991 noted that the top hospitalization diagnoses seen by rheumatology consult services in descending order were inflammatory polyarthritis, degenerative arthritis, seronegative spondyloarthritis, soft tissue rheumatism,

skeletal abnormality, and gout.⁴⁶ In contrast, data from a U.S. academic center published in 2001 noted that the five top reasons for rheumatology consultations at a university hospital were vasculitis, lupus, gout, rheumatoid arthritis, and soft tissue rheumatic conditions.⁴⁷ Patient demographics played a role in the diagnosis. Data from veterans' hospital consultations revealed that the most common diagnoses were crystalline arthritis and noninflammatory regional musculoskeletal conditions.⁴⁷ Hence arthritis and polyarthritis often occur in the inpatient setting and frequently require rheumatologic consultation. The diagnostic challenge is to discern whether new-onset polyarthritis is a consequence of the primary diagnosis, comorbidity, changing immunocompetency or metabolic state, or current drug therapy. Osteoarthritis, gout, and fibromyalgia account for a majority of such cases.

Infection and Polyarthritis

Infection as a cause of polyarthritis should always be considered in patients who present acutely with symptoms. Bacteria, viruses, and atypical microorganisms may cause polyarthritis directly as a pathogen or indirectly through an immune-mediated response (see Chapters 109 through 115). Bacteria that have been associated with polyarthritis include staphylococci, streptococci, enterococci, *Neisseria gonorrhoeae*, *Borrelia burgdorferi*, and gram-negative bacilli.⁴⁸ Certain viruses can also cause polyarthritis; these include parvovirus B19, mumps, rubella, hepatitis B and C viruses, cytomegalovirus, Epstein-Barr virus, HIV, and certain enteroviruses.⁴⁹ In addition, arboviruses (e.g., insect-transmitted viruses) have been associated with polyarthritis. Severe cases of debilitating polyarthritis have been associated with the Chikungunya virus, for which human epidemics have been reported in Africa, Asia, and certain parts of Europe. A detailed travel history may help guide specific testing for diseases endemic to the region. Although vigilance for infection is important in instituting appropriate therapy, this fact should be balanced by thoughtful clinical assessment based on history and examination before extensive testing is ordered.

Polyarthritis, Rash, and Fever

The triad of fever, arthritis, and rash may pose a challenge to the clinician. Differential diagnoses to consider include autoimmune (e.g., SLE, dermatomyositis, vasculitis), infectious (e.g., disseminated gonococcal infection), reactive, or inflammatory processes (e.g., serum sickness reaction, rheumatic fever, adult-onset Still's disease), and cryopyrin-related diseases (see specific chapters related to these individual diseases). Careful history and detailed physical examination may provide clues to the diagnosis.

Drug-Induced Syndromes

Despite the potential benefits of medications, certain adverse effects manifest as musculoskeletal complaints that mimic a primary rheumatologic disease. Best characterized are the agents that give rise to drug-induced lupus. Several drugs have been linked to lupus-like features, including hydralazine, procainamide, isoniazid, propylthiouracil,

sulfonamides, quinidine, tumor necrosis factor inhibitors, and minocycline.⁵⁰ Drug-induced lupus may present with myalgias, arthralgias, arthritis, or systemic complaints of fever, skin rash, pleuropulmonary disease, or cytopenias; a positive ANA test is required for diagnosis. Renal and neurologic features and double-stranded DNA (dsDNA) antibodies are usually absent. Seropositivity alone is not sufficient to make this diagnosis because only a fraction of patients who become seropositive (e.g., ANA positive) on an offending drug will develop lupus-like clinical features. Symptoms can appear weeks to months after exposure to the offending drug. The diagnosis is established by findings of lupus-specific features and ANA seropositivity while the patient is receiving an offending agent, and remission upon withdrawal of the agent.

Malignancy-Related Polyarthritis

Rheumatic symptoms associated with cancer may be difficult to distinguish from true rheumatologic disease.⁵¹ Symptoms typically are not related to direct tumor invasion or metastatic disease, but instead result from a paraneoplastic process. Patients may present with hypertrophic osteoarthropathy, carcinomatous polyarthritis, dermatomyositis/polymyositis, polymyalgia, or vasculitis. Rheumatic manifestations suggestive of an occult malignancy may include rapid onset of an unusual inflammatory arthritis, clubbing, diffuse bone pain typically in patients older than 50 years of age, chronic unexplained vasculitis, refractory fasciitis, Raynaud's syndrome unresponsive to vasodilator therapy, rapidly progressive digital gangrene, or Lambert-Eaton myasthenic syndrome.⁵² Rheumatic symptoms may coincide with or antedate the diagnosis of malignancy, with a typical course coinciding with that of the primary tumor. Prompt recognition is important so prompt treatment for the malignancy can be instituted, but extensive searching for an occult malignancy in most rheumatic syndromes is not advised unless accompanied by suggestive findings.⁵³

Pediatric Polyarthritis

Young patients who present with musculoskeletal complaints may be dismissed as having growing pains or symptoms attributed to a sports injury. Rheumatic diseases of childhood can be challenging to diagnose and may include juvenile idiopathic arthritis, ankylosing spondylitis, psoriatic arthritis, arthritis of inflammatory bowel disease, reactive arthritis, SLE, systemic sclerosis, vasculitis, Kawasaki disease, Henoch-Schönlein purpura, Lyme disease, septic arthritis, acute rheumatic fever, infective endocarditis, and human parvovirus B19 infection. Tracking pediatric arthritis has been difficult. In 2007, the CDC and the ACR collaborated to publish a report on the prevalence of significant pediatric arthritis and other rheumatologic conditions (SPARC) in the United States.⁵⁴ The calculated prevalence rate of SPARC was 403 per 100,000 (95% confidence interval [CI], 257 to 548 per 100,000); the top five diagnoses were listed as synovitis and tenosynovitis, myalgia and myositis (includes fibromyalgia), osteoarthritis and allied disorders, diffuse diseases of connective tissue, and rheumatoid arthritis and other inflammatory arthropathies.⁵⁴

Polyarthritis in the Elderly

Evaluating geriatric patients may be challenging because symptoms are often accompanied by nonspecific general complaints related to normal aging, medication side effects, or comorbid illnesses. Gerontorheumatologic diseases that should not be overlooked include late-onset rheumatoid arthritis, polymyalgia rheumatica, remitting seronegative symmetric synovitis with pitting edema (RS3PE) syndrome, giant cell arteritis, and paraneoplastic rheumatic syndrome. Often, patients present with polyarticular chondrocalcinosis of uncertain significance. Nonetheless, pseudogout, gout, and drug-induced disorders are common in the elderly. Laboratory testing, including synovial fluid analysis, may be helpful in diagnosis.

OUTCOME: A WINDOW OF OPPORTUNITY

Treatment of polyarthritis is tailored according to the underlying disease process; once persistent inflammatory arthritis is recognized, timely intervention is essential to halt the inflammatory process to prevent or postpone permanent joint damage. Several studies have found that a substantial number of patients who have unclassified inflammatory polyarthritis go into remission after 1 to 2 years.^{29,42-44} The difficulty lies in identifying those who will have persistent, destructive disease. Hence, early referral to a rheumatologist for prompt evaluation and initiation of appropriate therapy is essential for limiting damage. If treatment is delayed in those with poor prognostic indicators (e.g., positive RF, ACPA, evidence of radiographic damage, disease duration >6 weeks), the opportunity to improve outcome may be missed. Many studies have shown that early institution of aggressive disease-modifying antirheumatic drugs (DMARDs) in early inflammatory arthritis improved disease activity scores, pain, function, and radiologic scores, and allowed a chance at remission.⁵⁵⁻⁵⁸ Yet the potential side effects of these drugs must be reviewed when the decision is made to prescribe them to patients; no therapeutic algorithms are available for patients with unclassified inflammatory arthritis. The approach of managing inflammation and controlling symptoms is essential for these patients. Standard protocol should dictate classifying patients as having slowly progressive or aggressive destructive disease. Stratification should be based on prognostic indicators (Table 42-4) such as the presence of RF or CCP seropositivity, extended duration of disease, and radiographic evidence of joint destruction. In addition, for all patients, nonpharmacologic therapies should be initiated early; treatments include patient education, physical and occupational therapy with emphasis on joint protection, and maintenance of joint function.

CONCLUSION

Evaluating and diagnosing polyarthritis is challenging. This chapter establishes the importance of prompt evaluation, early referral, and expedient initiation of therapy. The clinician should consider common forms of polyarthritis first, and should assess patient age and sex, chronology,

Table 42-4 Factors Predicting Persistent and Erosive Arthritis

Variable	Odds Ratio for Persistent Arthritis	Odds Ratio for Erosions Given Persistence
Symptom duration		
≥6 weeks, <6 months, ≥6 months	2.49	0.96
Morning stiffness ≥1 hour	5.49	1.44
Arthritis in ≥3 joint groups	1.96	1.96
Pain with bilateral MTP squeeze	1.73	1.73
IgM RF ≥5 IU	1.65	3.78
Anti-CCP ≥92 IU	2.99	2.99
Erosions on hand/foot radiographs	4.58	4.58
	2.72	Infinite

background history, presence of extra-articular manifestations, and pattern of joint involvement when formulating a differential diagnosis. Only after careful consideration of these factors should clinicians proceed with additional investigations to confirm their suspicions. Without an established diagnosis, the patient's complaints should be managed in a symptom-driven fashion with frequent evaluations. As the disease evolves, additional investigative measures may be required.

The Skin and Rheumatic Diseases

LELA A. LEE • VICTORIA P. WERTH

KEY POINTS

Many systemic rheumatologic conditions present with skin findings.

The differential diagnosis for skin findings may require a skin biopsy for clinical-pathologic correlation.

Systemic steroids should be avoided if possible in psoriasis because flaring may occur with tapering of systemic glucocorticoids.

New biologic therapies have substantially improved care of patients with severe and resistant psoriasis.

The neutrophilic dermatoses comprise a group of inflammatory diseases including pyoderma gangrenosum and Sweet's syndrome, which can be associated with autoimmune diseases.

Patients with lupus erythematosus can have a wide variety of lupus-specific and lupus-nonspecific skin lesions.

Lupus-nonspecific skin lesions are more frequently seen in patients with systemic lupus erythematosus.

Patients with dermatomyositis frequently have pathognomonic skin lesions that may be seen in the absence of muscle disease.

Antimalarials may be of benefit for patients with morphea.

DIAGNOSIS OF SKIN LESIONS ASSOCIATED WITH RHEUMATIC DISEASES

The skin is a highly visible organ that is frequently affected in rheumatic diseases, and the presence of skin lesions may be helpful diagnostically. Certain caveats are worth noting before discussing the specifics. First, a major pitfall for the nondermatologist in evaluating skin lesions is incomplete knowledge of the entities in the differential diagnosis. For example, malar erythema occurs frequently in patients with systemic lupus erythematosus (SLE), but the differential diagnosis for malar erythema is rather extensive and includes conditions that are much more prevalent than lupus (e.g., rosacea), as well as conditions that are far less prevalent (e.g., Rothmund-Thomson syndrome). Patients frequently have more than one skin condition, which often makes diagnosis more challenging.

Another caveat for the nondermatologist concerns skin biopsy. Being able to determine when a skin biopsy is likely to be diagnostically useful in many cases requires a great deal of specialized knowledge, as does the interpretation of pathology reports. It is often the case with inflammatory

skin conditions that the microscopic findings are actually less diagnostically specific than is the clinical examination. Unfortunately, it is common for a pathology report to list a diagnosis without providing context regarding how definitive were the findings. For example, a skin biopsy report may have psoriasis listed as the final diagnosis, but, depending on the specific case, the unstated additional possibilities may include nummular dermatitis, atopic dermatitis, seborrheic dermatitis, lichen simplex chronicus, dermatophytosis, or drug eruption. Particularly with regard to inflammatory skin conditions, having a working knowledge of both dermatopathology and dermatology and placing the histologic findings in the context of the clinical presentation may be necessary to arrive at the correct diagnosis.

The above considerations notwithstanding, it is clearly useful for the physician caring for patients with rheumatic diseases to be well versed in their cutaneous manifestations. In this chapter, we provide an overview of these manifestations, as well as perspective on diagnosis and differential diagnosis. Therapy is discussed briefly in conditions where treatment may be specifically directed toward the skin lesions. Etiology and pathogenesis of these diseases are covered elsewhere in this text.

PSORIASIS

Psoriasis is one of the most common inflammatory skin diseases, affecting about 2% of the general population. There is a wide range of severity of skin lesions, from a few relatively asymptomatic plaques to extensive, disabling disease. The onset may be at any time during life. Once present, it may exhibit exacerbations and remissions, but it does not tend to resolve permanently. In general, onset in childhood portends more severe disease.

Skin lesions of psoriasis characteristically are sharply demarcated plaques with silvery scale and underlying erythema, although there may be a paucity of scale if the lesions have been partially treated or if they occur in intertriginous areas. When the scale is removed, pinpoint bleeding may be observed (Auspitz sign). Lesions may occur in areas of trauma (Koebner phenomenon) such as in surgical scars. In some cases lesions contain small pustules.

General phenotypes of psoriasis are chronic plaque, guttate, localized pustular, generalized pustular, and erythroderma.¹ Chronic plaque and guttate psoriasis are the most common, and generalized pustular psoriasis and erythroderma typically the most disabling and even life threatening. Chronic plaque psoriasis lesions are often relatively large in diameter and occur preferentially on elbows, knees, scalp, genitalia, lower back, and the gluteal cleft, although they may occur at many other locations. It is quite common

Figure 43-1 Guttate psoriasis resembles “drops” of discrete scaly papules with erythema, often on the trunk. (Courtesy Dr. Nicole Rogers, Tulane University Department of Dermatology, New Orleans.)

for only one area of skin such as the scalp to be affected. Guttate lesions are relatively small in diameter and usually quite numerous, distributed preferentially on the trunk and proximal extremities (Figure 43-1). Guttate psoriasis occurs relatively commonly in children and young adults, often manifesting a few weeks after a streptococcal infection.

Nail changes are common, occurring in about half of patients, and are often mistaken for fungal infection. Specific changes include pitting, onycholysis (“oil spots”), dystrophy of nails, and loss of the nail plate. These changes are not specific for psoriasis. Notably, pitting may occur as a result of trauma, and the finding of a few pits in the nails may not be helpful diagnostically. Nail changes are more frequent in patients with arthritis of the distal interphalangeal joints.²

Arthritis occurs more often in patients with severe cutaneous disease, but cutaneous disease need not be present at all. Remissions and exacerbations of arthritis do not correlate well with remissions and exacerbations of skin disease. The presence of psoriatic skin lesions may be helpful in supporting a diagnosis of psoriatic arthritis, although many patients with psoriasis have joint disease unrelated to psoriasis.

The diagnosis of psoriatic skin disease is usually made on clinical grounds alone, largely on the basis of the morphology and distribution of lesions. The differential diagnosis may be extensive and includes in selected cases nummular eczema, seborrheic dermatitis, candidiasis (in intertriginous areas), pityriasis rubra pilaris, Bowen’s disease or Paget’s disease (for isolated plaques), drug eruption, pityriasis rosea, pityriasis lichenoides, dermatophytosis, lichen planus, secondary syphilis, parapsoriasis, cutaneous lupus (especially subacute cutaneous lupus erythematosus [SCLE]), and dermatomyositis. In cases where the diagnosis is not clear-cut, biopsy may be helpful. The histologic findings may range from virtually diagnostic for psoriasis to merely consistent with but not diagnostic. Histologically, psoriasis cannot generally be distinguished from the skin lesions seen in reactive arthritis.

Common topical therapies include corticosteroids, tar, anthralin, calcipotriene, and tazarotene.³ Phototherapy

using sunlight, broadband ultraviolet B (UVB), narrowband UVB, or psoralen ultraviolet A-range (PUVA) is still a mainstay of therapy for many patients. Common systemic therapies include methotrexate, acitretin, cyclosporine, and the relatively new biologic agents such as etanercept, adalimumab, infliximab, and ustekinumab. Cyclosporine may be useful to attain relatively rapid control of severe psoriasis, but it is less often used as a long-term therapy. Although topical corticosteroids are an acceptable treatment for many patients, systemic corticosteroids are avoided for the treatment of cutaneous disease, in particular due to the observation of severe flaring of psoriasis following withdrawal of systemic corticosteroids.

REACTIVE ARTHRITIS

The diagnosis of reactive arthritis may be rather straightforward in a young male who develops urethritis, conjunctivitis, and arthritis following an episode of nongonococcal urethritis. However, in many cases the clinical features are not fully expressed and cutaneous lesions may be helpful in establishing the diagnosis.⁴

Circinate balanitis is the most common of the characteristic mucocutaneous lesions. Small erythematous papules and pustules coalesce to form serpiginous erosive or crusted plaques on the glans penis. In uncircumcised men, the appearance is more often that of erosion rather than crust because the moisture and trauma minimize the formation of crust. In circumcised men, crusting may be more obvious than erosion.

The palms and, particularly, the soles may develop lesions that are initially similar to the small erythematous papules and pustules of the genital region. With time, these lesions, termed *keratoderma blennorrhagica*, tend to become markedly hyperkeratotic (Figure 43-2). They may coalesce into large plaques or generalized hyperkeratosis involving the entire plantar surface, or they may remain discrete, erythematous, hyperkeratotic papules a few millimeters in diameter.

Figure 43-2 Reactive arthritis with *keratoderma blennorrhagica* of the feet.

Erythematous, scaly plaques indistinguishable from psoriasis may appear elsewhere on the skin including the scalp, elbows, and knees. When lesions occur around the nails, it is common for there to be hyperkeratosis underneath the nails. Pitting is not typical of reactive arthritis, but thickening, ridging, or shedding of the nail plate may occur. Erosions of the oral mucosa are relatively common on the tongue, buccal mucosa, and palate.

The diagnosis of the cutaneous lesions is usually made on a clinical basis. Skin biopsy may be helpful in excluding many entities in the differential diagnosis but generally cannot exclude psoriasis. Unfortunately, the major condition in the differential diagnosis of the skin lesions is usually psoriasis. One somewhat distinguishing histologic feature is that the older lesions of keratoderma blennorrhagica may have a considerably thickened stratum corneum, corresponding to the markedly hyperkeratotic papules seen grossly.

For the genital lesions, conditions to consider in the differential diagnosis may include candidiasis, psoriasis, dermatitis, Bowen's disease, Paget's disease, squamous cell carcinoma, Zoon's balanitis, erosive lichen planus, lichen sclerosus (balanitis xerotica obliterans), aphthosis, fixed drug eruption, and certain infectious diseases. The differential diagnosis for lesions on the soles and palms may include psoriasis, hereditary or acquired hyperkeratosis of the palms and soles, pustular eruption of the palms and soles, pompholyx, scabies, and dermatophytosis. The differential diagnosis for oral lesions may include geographic tongue, lichen planus, candidiasis, aphthae, and autoimmune bullous diseases.

The approach to treatment of skin lesions is similar to that for psoriasis, particularly in cases where the lesions are persistent. Choice of topical therapies may be somewhat limited due to the sites involved. The oral mucosa is a difficult site to deliver medication topically, and the genital area may develop irritant reactions to certain topical medications. Often, topical corticosteroids are preferred for both areas because of low potential for irritation and the availability of topical preparations designed for these sites. In the genital area, suprainfection with *Candida* may occur and concurrent therapy with a topical or systemic anticandidal medication may be necessary on occasion.

RHEUMATOID ARTHRITIS

The major skin manifestations associated with rheumatoid arthritis (RA) generally fall under granulomatous lesions, exemplified by the rheumatoid nodule, and neutrophilic lesions, exemplified by vasculitis and pyoderma gangrenosum.

Rheumatoid nodules are the most common cutaneous manifestations of RA.⁵ They occur more often in seropositive patients and correlate somewhat with higher rheumatoid factor titers, more severe arthritis, and increased risk for vasculitis. Nodules are usually relatively deep, firm, and painless and tend to develop over areas of pressure and trauma such as the extensor forearms, fingers, olecranon processes, ischial tuberosities, sacrum, knees, heels, and posterior scalp (Figure 43-3). In patients who wear glasses, nodules may develop under the bridge or nosepieces. In most cases, rheumatoid nodules are in the subcutaneous

Figure 43-3 Rheumatoid nodule over the extensor tendon of the distal interphalangeal joint.

tissue and/or deep dermis, but occasionally they may occur more deeply or more superficially.

Clinically, depending on the presentation, numerous entities may be in the differential diagnosis including infections, inflammatory disorders, and benign tumors. If needed, biopsy of a nodule may be quite helpful in establishing the diagnosis. Rheumatoid nodules exhibit a distinctive histologic finding called necrobiosis, a fibrinoid degeneration of the connective tissue, surrounded by palisaded histiocytes. Necrobiosis is also a characteristic feature of granuloma annulare and necrobiosis lipoidica diabetorum. Although necrobiosis lipoidica diabetorum is easily distinguished from rheumatoid nodule clinically, the subcutaneous variant of granuloma annulare may be difficult to distinguish, both clinically and histologically.

The term *rheumatoid nodulosis* has been used to describe an entity characterized by subcutaneous rheumatoid nodules, cystic bone lesions, rheumatoid factor positivity, and arthralgias in patients with little or no evidence of systemic manifestations of RA or erosive joint disease.⁶ Older males are preferentially affected.

The development of nodules in RA patients undergoing treatment with methotrexate has been noted by several observers and termed *accelerated rheumatoid nodulosis*.⁷ The nodules are newly appearing and occur preferentially on the hands. There are also case reports of the phenomenon in RA patients treated with etanercept.

The other major type of cutaneous lesion associated with RA is neutrophil predominant. Rheumatoid vasculitis occurs more frequently in patients who are seropositive and have rheumatoid nodules, and it often occurs relatively late in the course of the disease.⁸ Vessels of any size may be affected. In the skin, vasculitis may appear as purpuric papules and macules, nodules, ulcerations, or infarcts. Bywaters' lesions are periungual or digital pulp purpuric papules representing a small vessel vasculitis, but not necessarily associated with vasculitic lesions elsewhere.

The differential diagnosis of purpuric or petechial lesions may include stasis dermatitis, Schamberg's purpura, platelet dysfunction, petechial drug eruptions, viral exanthems, emboli, thromboses, and sludging. Of these, Schamberg's purpura, a relatively common condition unassociated with systemic disease, is probably the most frequently confused

with small vessel vasculitis. Skin biopsy may be helpful in establishing the diagnosis of vasculitis, particularly if an early lesion is sampled, although rheumatoid vasculitis cannot be distinguished histologically from many other causes of small vessel vasculitis. Immunofluorescent examination of an early lesion may be helpful in ruling out IgA-predominant vasculitis. The differential diagnosis of ulcers and infarcts is extensive. Biopsy is often unrewarding because nonspecific changes present in established lesions may make interpretation difficult, but on occasion biopsy of ulcers or infarcts may result in a definitive diagnosis of vasculitis.

The neutrophilic dermatoses are a group of diseases inflammatory rather than infectious in origin, typified by pyoderma gangrenosum and Sweet's syndrome. These conditions have been associated with a variety of extracutaneous diseases including RA. The classic pyoderma gangrenosum lesion is a rapidly appearing, large, destructive ulcer in which the border is undermined. The classic lesion of Sweet's syndrome is an erythematous, edematous plaque with a surface often described as mammillated, pseudovesicular, or microvesicular. Clinical appearances intermediate between these two have been described. For pyoderma gangrenosum, the differential diagnosis is usually that of conditions causing leg ulcer, and the diagnosis is mainly clinical, with biopsy primarily serving to exclude some of the other entities under consideration. For Sweet's syndrome, the differential diagnosis may include infections, halogenoderma, and other neutrophilic dermatoses. Biopsy often provides helpful supporting evidence. The mainstay of therapy for acute lesions of both conditions is systemic corticosteroids. For more persistent lesions, a variety of options may be considered, cyclosporine and infliximab being two of the more common. Colchicine or potassium iodide may be first-line therapies for Sweet's syndrome, particularly in patients with infections or contraindications to corticosteroids.

The term *rheumatoid neutrophilic dermatitis* has been given to describe chronic, erythematous, urticarial-like plaques that occur primarily on the distal arms.⁹ Clinically and histologically, rheumatoid neutrophilic dermatitis is similar to Sweet's syndrome and may be a variant of it.

Palisaded neutrophilic and granulomatous dermatitis (PNGD) of connective tissue disease is an unusual condition or set of conditions for which consistent terminology is still evolving. As the name implies, the major bases for diagnosis of this entity are the histologic appearance and the occurrence in a patient with connective tissue disease, often RA.¹⁰ The clinical appearance ranges from erythematous or flesh-colored papules that appear primarily on fingers and elbows to erythematous or flesh-colored linear cords on the trunk. Some authors classify the latter as interstitial granulomatous dermatitis with cutaneous cords or interstitial granulomatous dermatitis with arthritis (IGDA). Treatment of PNGD and IGDA can be challenging. PNGD may respond to dapsone or sulfapyridine. IGDA can be treated with antimalarials or immunosuppressives, but because this is both a newly described and relatively infrequent condition, all evidence is based on case reports and small case series. Patients can progress to a severe deforming arthritis. In some cases, granuloma annulare and rheumatoid nodule may be in the differential diagnosis.

JUVENILE RHEUMATOID ARTHRITIS/STILL'S DISEASE

The majority of patients with classic Still's disease manifest an exanthematous eruption coincident with daily fever spikes.¹¹ The lesions are evanescent, usually nonpruritic, erythematous macules occurring over the trunk, extremities, and face. The differential diagnosis includes viral exanthem, drug eruption, familial periodic fever syndromes, and rheumatic fever. It is not unusual for exanthems of any type to be more prominent during fevers, but it is not expected that viral exanthems and drug eruptions clear completely between fever spikes. However, it should be noted that the eruption of erythema infectiosum (fifth disease) due to parvovirus B19 may resolve completely but reappear when the skin temperature rises, as with warm baths or exercise. Adult-onset Still's disease is also typified by an evanescent erythematous, sometimes salmon-colored eruption over the trunk and extremities, associated with high fever. Skin biopsy may be nonspecific. However, there has been a report of a unique histologic pattern consisting of dyskeratotic keratinocytes in the upper epidermis along with increased dermal mucin in adult-onset Still's disease.¹² The frequency with which this histologic pattern is present in Still's disease remains to be determined.

Subcutaneous nodules may develop in both juvenile-onset and adult-onset Still's disease. The lesions tend to occur at the same sites of the body, as do rheumatoid nodules in RA, but histologically they appear similar to nodules of rheumatic fever.

LUPUS ERYTHEMATOSUS

The skin is involved at some time in the course of disease in the majority of patients with lupus erythematosus (LE), and skin lesions may be important in establishing the diagnosis. Some skin lesions are highly likely to be associated with "systemic" (i.e., extracutaneous) disease, whereas others may or may not be associated with extracutaneous disease. The phenomenon of lupus skin lesions occurring in the absence of systemic disease has previously been termed *discoid lupus* by some. However, dermatologists use this term to denote a specific type of skin lesion, regardless of presence or absence of systemic disease. It is the latter meaning of discoid lupus to which we refer in this chapter.

Lupus-Specific Skin Lesions

James Gilliam classified cutaneous lesions as being specific or nonspecific for lupus, discoid lupus lesions being an example of the former and palpable purpura being an example of the latter.¹³ Although this division of lesions is useful, sometimes a lupus-specific lesion occurs in a patient whose primary autoimmune disease is something other than LE. For example, SCLE lesions may occur in patients whose primary condition is Sjögren's syndrome, and discoid lesions may be seen in a variety of conditions such as mixed connective tissue disease. Many of the lupus-specific skin lesions can occur in patients who have no evidence of extracutaneous disease.

The characteristic morphologies of the various lupus-specific skin lesions are in large part a function of the depth

and intensity of the inflammatory infiltrate, presence or absence of epidermal basal cell damage, involvement of hair follicles, abundance of dermal mucin, and tendency to scar. In practice, there may be some overlap of these features and there may be more than one type of lesion present in a given patient, making classification difficult. Because therapy for most of the lupus-specific lesions is similar, it is not always important to distinguish among the various types of lesions. However, it can be useful to identify conditions that are more likely to scar, in order to target more aggressive therapy, and to identify conditions that are highly likely or highly unlikely to be associated with systemic disease.

Acute cutaneous lupus (ACLE) lesions are typified by malar erythema, the classic butterfly rash (Figure 43-4). The inflammation tends to be superficial, with little propensity to scar. Precipitation or exacerbation of lesions by sun exposure is common, and lesions tend to be distributed on the sun-exposed face, neck, extensor arms, and dorsal hands, where the skin over the knuckles is relatively spared. Often the lesions are quite transient, but they may be persistent. When the face is severely affected, facial edema may be prominent. Oral lesions are often present concurrently. Acute eruptions with considerable focal basal cell damage can result in erythematous papules with dusky centers that clinically mimic erythema multiforme. The major importance of recognition of ACLE is its strong association with systemic disease. The differential diagnosis of malar rash may include several conditions. In some cases, the facial rash of ACLE may be difficult to distinguish from rosacea. Seborrheic dermatitis, atopic dermatitis, and photosensitive eruptions such as polymorphous light eruption and drug-induced photosensitivity may also be considered. Dermatomyositis may cause a photosensitive facial erythema with edema similar to ACLE, although the erythema tends to be more violaceous. Persistent lesions on the neck and arms may be indistinguishable from SCL. Discoid lupus lesions occasionally appear in a butterfly distribution, where they can result in disfiguring scarring. Skin biopsy is usually not performed on malar erythema because of its transient character, the scar resulting from biopsy, and the availability of other means of establishing the diagnosis of SLE. If a biopsy is done, it should be noted that dermatomyositis and SCL

Figure 43-4 Acute malar rash in a butterfly distribution in systemic lupus erythematosus.

Figure 43-5 Subacute cutaneous lupus erythematosus: annular-polycyclic type.

cannot be distinguished from ACLE by histology and also that skin biopsy findings are sometimes nonspecific.

SCL is a photosensitive eruption usually associated with anti-Ro/SSA autoantibodies.¹⁴ Lesional morphology is of two main types, annular erythematous plaques and scaly erythematous psoriatic plaques. Lesions are distributed over sun-exposed skin of the arms, upper trunk, neck, and sides of the face (Figure 43-5). Inexplicably, the midfacial area is usually uninvolved. Fair-skinned individuals are preferentially affected. Lesions may resolve with hypopigmentation or even depigmentation, but they rarely scar. Several drugs, particularly hydrochlorothiazide, have been reported to induce SCL.¹⁵ The risk for development of systemic disease is not fully known, but perhaps 15% or so of patients with SCL have or will develop significant systemic disease, often SLE, Sjögren's syndrome, or an overlap. Depending on the morphology of the lesions and the clinical presentation, the differential diagnosis may include psoriasis, tinea, polymorphous light eruption, reactive erythema, and erythema multiforme. Skin biopsy for routine histology is often helpful in establishing the diagnosis. The characteristic finding of skin biopsy for immunofluorescence is a particulate deposition of immunoglobulin G (IgG) in the epidermis (Figure 43-6) both in lesions and uninvolved skin.¹⁶ This

Figure 43-6 Direct immunofluorescence (lupus band test).

Figure 43-7 Discoid lupus erythematosus of the scalp, with scarring alopecia and central hypopigmentation. (Courtesy Dr. Nicole Rogers, Tulane University School of Medicine, New Orleans.)

pattern can be reproduced in animal models by infusing anti-Ro, and thus immunofluorescence results provide information that duplicates serologic testing for anti-Ro.¹⁷ The particulate epidermal pattern seen in normal skin does not carry the same implication for increased risk of having SLE, as does the finding of granular deposits of IgG at the dermal-epidermal junction (the nonlesional lupus band test). It should be noted that many immunofluorescence laboratories do not routinely report epidermal findings.

Discoid lupus erythematosus (DLE) lesions are the most common of the persistent lupus-specific skin lesions. Active lesions are erythematous papules and plaques that feel indurated to palpation because of the substantial numbers of inflammatory cells infiltrating the dermis. Involvement of hair follicles may be grossly evident as follicular plugs and scarring alopecia. Dyspigmentation is common, often with hypopigmentation or even depigmentation in the center and hyperpigmentation at the periphery (Figure 43-7). Visible scale is common and occasionally is pronounced in a clinical variant called *hypertrophic DLE*. In established lesions, scarring may be disfiguring. Lesions tend to occur on the scalp, ears, and face but may be widespread and occasionally involve mucosal surfaces. It is unusual to have lesions below the neck in the absence of lesions above the neck.¹⁸ Sun exposure may exacerbate DLE in some cases, but the presence of lesions in sun-protected areas of the scalp and ears and the frequent absence of a history of photosensitivity indicates that sun exposure is probably not a trigger in every instance. There are case reports of squamous cell carcinoma developing in established DLE lesions. In a patient who presents with DLE lesions, the risk for developing SLE is probably about 5% to 10%, although mild systemic symptoms such as arthralgias are relatively common. The differential diagnosis of DLE lesions is often that of conditions exhibiting intense lymphocytic or granulomatous infiltrates such as sarcoid, Jessner's lymphocytic infiltrate, granuloma faciale, polymorphous light eruption, lymphocytoma cutis, and lymphoma cutis. In the scalp, lichen planopilaris and other scarring alopecias may be considered. Skin biopsy for routine histology often establishes the diagnosis definitively. In more difficult cases, biopsy for

immunofluorescence may provide additional supporting diagnostic information. Lesions are expected to have granular deposits of immunoglobulins at the dermal-epidermal junction. Unless there is concomitant systemic disease, normal skin is expected not to have immunoglobulin deposits.

Tumid lupus (TLE) skin lesions are similar to DLE lesions in that they are erythematous indurated papules and plaques with a substantial lymphocytic infiltrate. Unlike DLE, though, the lesions do not exhibit epidermal abnormalities, follicular involvement, or scarring. Considerable mucin is present in the dermis, giving the lesions a somewhat boggy look and feel. In some reports, lesions are most common on the face and may be reproduced by phototesting.¹⁹ The risk for SLE appears to be low, and immunoglobulin deposits are not generally present in skin biopsies. Jessner's lymphocytic infiltrate and other lymphocytic and granulomatous infiltrative conditions (see earlier) are in the differential diagnosis. Skin biopsy for routine histology is valuable in establishing the diagnosis, with the exception of reliably distinguishing TLE from Jessner's lymphocytic infiltrate. Some have argued that Jessner's lymphocytic infiltrate and TLE are one and the same, and it might reasonably be argued that what is called TLE is not appropriately classed as a form of chronic cutaneous LE but rather as an independent entity. However, the presence of TLE lesions in some patients with lupus is evidence to the contrary.

Lupus panniculitis (LEP) lesions have inflammation in the subcutaneous tissue, resulting in deep indurated plaques that become disfiguring, depressed areas (Figure 43-8). Usual sites of involvement are face, upper trunk, breasts, upper arms, buttocks, and thighs. The risk for SLE is not known precisely, but clearly some patients with LEP have or will develop SLE. The differential diagnosis is that of the panniculitides, but the distribution exhibited in LEP is unusual for most other conditions that cause panniculitis. The combination of clinical presentation and skin biopsy for histology usually serves to establish the diagnosis.

Some unusual variants of cutaneous lupus are chilblain lupus (red or dusky plaques on colder areas of skin such as fingers, toes, nose, elbows, knees, and lower legs), cutaneous lupus/lichen planus overlap, and a bullous eruption due to

Figure 43-8 Lupus profundus (panniculitis) with extensive atrophy.

autoantibodies to type VII collagen or other basement membrane zone proteins. Not all bullae related to lupus are due to autoantibodies to basement membrane proteins, however. It is not unusual to develop bullae simply from intensive destruction of the basal cell layer in ACLE, SCLE, or, rarely, DLE.

Treatment of the lupus-specific lesions is relatively similar for most of the subtypes, with some exceptions and modifications. Sun protection is critical for lesions that are initiated or exacerbated by sun exposure. Many or most patients underestimate the amount of sunscreen needed to apply, the potential damage of the seemingly minimal exposure one has in the course of day-to-day activities, and the value of protective clothing. Topical therapy is often used to avoid side effects of systemic medications or to provide adjunctive therapy, although topical agents are unlikely to be beneficial if the disease process is deep, as in panniculitis. Topical or intralesional corticosteroids are the most often used local therapy, but there are some reports of benefit from topical calcineurin inhibitors and topical retinoids.^{20,21} The first-line systemic medication for cutaneous lupus is antimalarial therapy. Several reports indicate that smoking tobacco decreases the likelihood of response to antimalarials.²² For antimalarial-resistant skin disease, a wide variety of medications have been used but there is no clear second choice when antimalarials have not worked. Although dapsone is arguably not helpful in most types of cutaneous lupus, it may be helpful in neutrophil-predominant bullous eruptions.²³ Measures to keep the skin warm may be useful for chilblains lupus.

Nonspecific Cutaneous Lesions

A wide variety of lupus nonspecific skin lesions has been reported. Many of these such as vasculitic lesions are cutaneous clues to the possibility of extracutaneous disease. Noteworthy in this regard is livedo reticularis. The netlike erythema of livedo reticularis is a vascular phenomenon due to lowered oxygenation at the periphery of the area supplied by a particular vessel. This can simply be due to vasoconstriction, such as occurs in a cold environment, and thus can be a benign finding. If livedo is more prominent than usual, not corrected by warming, and persistent, it can indicate lowered flow due to pathology such as vasculitis, atherosclerotic disease, or sludging. In lupus, livedo reticularis may be a sign of the presence of antiphospholipid antibodies.²⁴

Other lupus nonspecific skin lesions include Raynaud's phenomenon, palmar erythema, periungual telangiectasia, alopecia, erythromelalgia, papulonodular mucinosis, and anetoderma. Sclerodactyly, calcinosis, and rheumatoid nodules have been reported but may be more likely in overlap syndromes than in SLE.

NEONATAL LUPUS SYNDROME

Neonatal lupus erythematosus (NLE) is associated with maternal IgG autoantibodies to Ro/SSA and La/SSB.²⁵ Affected children may have cutaneous lesions, cardiac disease (notably complete heart block and/or cardiomyopathy), hepatobiliary disease, or hematologic cytopenias. Most children have only one or two features of the disease.

Similar to the anti-Ro/SSA-associated SCLE of adults, the skin lesions are often photosensitive, have relatively superficial inflammatory infiltrates, and do not tend to scar. The lesions usually appear at a few weeks of age but have been noted at birth in several cases. The natural history of the skin disease is that the lesions last for weeks or months and resolve spontaneously, usually leaving no residuum. In a few cases, persistent telangiectasias have been noted. Individual lesions appear as erythematous annular papules or plaques. Lesions are usually more numerous and more intensely inflamed on the face and scalp but may additionally occur on the trunk and extremities. Confluent periorbital erythema, giving the appearance of an erythematous mask, is common and diagnostically helpful. Even though the skin disease resolves and most children without extracutaneous involvement remain otherwise healthy, there is a possibility that children who have had NLE are at increased risk for the development of autoimmune disease later in childhood.²⁶

Differential diagnosis of the skin lesions may include reactive erythema, drug eruption, erythema multiforme, and urticaria. Annular NLE lesions usually have little or no scale, unlike the annular lesions of tinea. In areas where there is intense destruction of the basal cell layer, lesions may be crusted and look similar to bullous impetigo. Treatment of skin lesions consists largely of sun protection and mild topical steroids.

The pathogenesis of lupus is covered elsewhere, but it is noteworthy that SCLE-like, anti-Ro/SSA-associated skin lesions may occur in neonates, but other lupus-specific skin lesions do not appear to be maternally transmissible.

SJÖGREN'S SYNDROME

The most common mucocutaneous findings of Sjögren's syndrome are related to glandular dysfunction. Lacrimal gland dysfunction causes dryness and irritation of the eyes and can lead to keratitis and corneal ulceration. Salivary gland dysfunction causes dry mouth and may result in angular cheilitis and numerous dental caries. Vaginal xerosis may cause burning and dyspareunia. The skin may be dry, cracked, and pruritic. Mildly dry mucous membranes and even severely dry skin may be present in a substantial percentage of normal individuals who live in dry climates, so the findings should be interpreted in the context of the setting. In Japanese patients with Sjögren's syndrome, an annular erythema has been described that is somewhat reminiscent of annular SCLE or annular lesions of NLE, although more indurated.²⁷

Vasculitis is a relatively common finding. In one series of 558 patients with primary Sjögren's syndrome, 52 had vasculitis, typically involving small vessels. In most cases, lesions were purpuric, but in some, urticarial vasculitis was the clinical presentation. Patients with cutaneous evidence of vasculitis generally had more severe systemic disease.²⁸

DERMATOMYOSITIS

The current ACR criteria for dermatomyositis (DM) do not recognize the existence of amyopathic dermatomyositis. This has led to a problem in diagnosing patients with predominantly skin involvement with DM. Amyopathic

Figure 43-9 Gottron's papules over the interphalangeal joints in dermatomyositis.

dermatomyositis (ADM), or dermatomyositis *siné* myositis, refers to classic cutaneous manifestations of DM without evidence of inflammatory myopathy. ADM has also been defined as biopsy-proven cutaneous findings of classic DM occurring for 6 months or longer without any clinical evidence of proximal muscle weakness, serum muscle enzyme abnormalities, or abnormal muscle testing. This latter definition excludes any patient treated with systemic immunosuppressive therapy for 2 or more consecutive months during the first 6 months of cutaneous manifestations of DM because therapy could suppress clinically significant myositis. It also excludes any patient using drugs that are associated with DM-like skin changes (e.g., hydroxyurea).²⁹

The most common cutaneous manifestations of active DM include Gottron's papules (Figure 43-9) and Gottron's sign, which are pathognomonic of DM. Other characteristic findings of DM include heliotrope rash of the periorbital and upper eye area (Figure 43-10), V- or shawl-shaped macular erythema over the chest and back, cuticular overgrowth, and periungual telangiectasias. Patients with active disease can have widespread erythema over the trunk and extremities, with accentuation of the extensor arms and legs, as well as lateral thighs. Erythema and scale of the scalp

Figure 43-10 Heliotrope eruption of dermatomyositis with characteristic edema.

can result in extensive alopecia. Hyperkeratosis of the palmar and lateral surfaces of the fingers, called *mechanic's hands*, can be associated with anti-Jo-1 autoantibodies and interstitial lung disease. Rarely patients can have a panniculitis. Vasculopathy, with livedo reticularis and ulceration, can occur. Itching can result in excoriations and lichenification. Damage lesions include postinflammatory hyperpigmentation, poikiloderma, calcinosis, lipoatrophy, and depressed scars.³⁰ Poikiloderma is a descriptive term for a pattern of finely mottled white areas and brown pigmentation, telangiectasia, and atrophy.

Skin biopsy from a patient with cutaneous DM is identical to that seen with cutaneous lupus erythematosus. A diagnosis of DM is made by clinical-pathologic correlation and does not need to include muscle disease. In the absence of clinical muscle findings, the workup for DM should include muscle enzyme testing, pulmonary function testing, chest radiograph, electrocardiogram, and evaluation for underlying malignancy. Patients with amyopathic DM have the same incidence of pulmonary involvement as classic DM, and about 25% of patients have evidence of pulmonary fibrosis on high-resolution CT.³¹ There has been an increased association of dermatomyositis including ADM with underlying malignancy. The most frequent malignancies are lung, ovarian, pancreatic, stomach, colorectal, and non-Hodgkin's lymphoma.³² The increased risk of malignancy occurs for at least 5 years after the diagnosis of DM, and thus patients should receive routine cancer screening during that time.³³ Patients with DM frequently experience a delay in obtaining a diagnosis, and the presence of photosensitivity, malar rash, oral ulcers, and a positive antinuclear antibody (ANA) test means that they frequently get misdiagnosed as having SLE, having met the current criteria for the disease.

The patients with both skin and muscle disease frequently experience resolution of their muscle disease after aggressive treatment with glucocorticoids, with or without immunosuppressives. Patients are sometimes treated with intravenous immunoglobulin (IVIG), cyclosporine, or tacrolimus. Patients with AMD or residual skin disease after treatment often benefit from hydroxychloroquine. Patients who do not improve with a single antimalarial can benefit from the addition of quinacrine or a switch from hydroxychloroquine to chloroquine.³⁴ Immunosuppressives like methotrexate, azathioprine, or mycophenolate mofetil can be of additive benefit for patients with resistant skin disease. IVIG can be of benefit for skin findings of DM, and studies related to the role of biologics in treatment are ongoing.³⁵

SCLERODERMA AND OTHER SCLEROSING CONDITIONS

Morphea

Scleroderma can occur as localized or systemic disease. The localized form of the disease occurs as localized or generalized morphea, linear scleroderma, or facial hemiatrophy, otherwise known as *Parry-Romberg syndrome*. Linear scleroderma can occur over the forehead, in a variant called *en coup de sabre* (Figure 43-11). Morphea is seen more in adults, with increased incidence with advancing age, whereas linear scleroderma occurs more frequently in children and

Figure 43-11 Linear scleroderma of the forehead. (Courtesy Dr. Victoria Werth, University of Pennsylvania Department of Dermatology and Philadelphia Veterans Administration Medical Center, Philadelphia.)

adolescents.³⁶ Although remissions are reported to occur in 3 to 5 years, ongoing clinical activity or reactivation is not unusual.

Localized scleroderma patients typically lack sclerodactyly, Raynaud's phenomenon, or internal organ involvement. The level of involvement in localized scleroderma can be in the dermis (morphea), fat (subcutaneous morphea), fat and fascia (morphea profundus), and fascia (eosinophilic fasciitis). Morphea typically has round and/or oval, irregular plaques that are initially dull red/violaceous, smooth, and indurated. They frequently progress to chalky, white atrophic lesions, although some patients have residual hyperpigmentation overlying the lesions. Morphea can have different presentations including an overlap with lichen sclerosus et atrophicus, where there are flat-topped papules that coalesce to form a white plaque, sometimes combined with a deeper morphea lesion. Some lesions are small and oval, known as *guttate morphea*. Occasionally patients with localized scleroderma overlap with other autoimmune diseases such as SLE. There are many mimickers of morphea including radiation-induced morphea, injection-induced morphea-like lesions, morphea-like Lyme disease seen in Europe, eosinophilia-myalgia syndrome, toxic oil syndrome, and more recently nephrogenic systemic fibrosis.

Linear scleroderma is frequently located on the lower limbs, upper limbs, frontal head area, and anterior trunk. It is frequently unilateral and can result in joint deformity, joint contractures, and limb atrophy. Some cases are associated with seizures or other focal neurologic symptoms. Parry-Romberg syndrome can occur in the first or second decade of life and leads to unilateral facial atrophy in 95%. Half of patients start as *en coup de sabre* and progress to soft tissue involvement in the upper face. Patients can have seizures, headaches, visual changes, and atrophy of the

salivary glands and hemiatrophy of the tongue on the same side as the facial atrophy. Any reparative surgical treatment should be timed to occur no sooner than 1 year after cessation of the ongoing atrophic process. ANAs are positive 46% of the time in localized scleroderma. A positive ANA correlates with disease severity.³⁷ A peripheral eosinophilia and hypergammaglobulinemia can be seen.

Treatment of localized scleroderma includes protection from trauma and cold, antimalarials (plaquenil alone, hydroxychloroquine and quinacrine together, or chloroquine with or without quinacrine), low-dose prednisone for eosinophilic fasciitis, topical calcipotriene, methotrexate, and mycophenolate mofetil.³⁸ Phototherapy with narrow band UVB, UVA1, PUVA, and topical photodynamic therapy has also been used.^{39,40}

Systemic Scleroderma

Patients with early limited cutaneous scleroderma have Raynaud's phenomenon for many years, minimal constitutional symptoms, puffy fingers, limited skin thickening, and anticentromere antibody. Patients with early diffuse cutaneous scleroderma frequently have delayed Raynaud's, acute onset, many constitutional symptoms, arthralgias, tendon friction rubs, swollen puffy hands, and early diffuse skin thickening. They may have anti-Scl-70 antibody, as well as anti-RNA polymerase III. The major and minor criteria for diffuse cutaneous scleroderma include many skin findings. Major criteria include proximal scleroderma. Minor criteria include sclerodactyly (Figure 43-12), digital pitting and scars of the fingertips, loss of substance of the finger pad, and bibasilar pulmonary fibrosis.⁴¹ Ischemia and skin changes in systemic scleroderma can result in skin ulcers. Therapies used in the cutaneous treatment of systemic scleroderma include D-penicillamine, methotrexate, cyclophosphamide, photopheresis, and bone marrow transplant.⁴²⁻⁴⁴ Treatment of Raynaud's phenomenon is covered elsewhere. There are reports of bosentan, an endothelin receptor antagonist, and phosphodiesterase inhibitors such as sildenafil being helpful in the treatment of skin ulcers.^{45,46} Patients who have pruritus may benefit from systemic antihistamines.

Figure 43-12 Sclerodactyly with flexion contractures.

Eosinophilic Fasciitis

Eosinophilic fasciitis (EF) involves inflammation of the fascia overlying muscle and results in swelling of the extremities, followed by fibrosis and contractures. The digits are typically spared. There is often a rapid onset of disease activity, particularly following physical exertion. A contaminant of L-tryptophan was associated with an EF-like disease in the early 1990s.⁴⁷ Approximately 30% of EF patients have morphea concurrently.

Diagnosis is based on a deep, usually excisional biopsy of the skin that includes fascia. There are inflammatory cells among collagen bundles, thickening of collagen, sclerosis of the dermis and fat/fascia, and absent sweat glands and hair.

POEMS Syndrome

POEMS syndrome includes polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes. Polyneuropathy and a monoclonal plasmaproliferative disorder must be present along with one other minor criterion including sclerotic bone lesions, Castleman's disease, organomegaly, edema, endocrinopathy, papilledema, or skin changes. Other associated findings may include ascites, pleural effusions, thrombocytosis, fingernail clubbing, and white nails. The sensorimotor polyneuropathy has both demyelinating and axonal features and is slowly progressive and debilitating in most cases. Organomegaly may be hepatosplenomegaly or lymph node enlargement. Endocrinopathies include diabetes, impotence, gynecomastia, and hypothyroidism. The monoclonal (M) protein abnormality consists of IgA or IgG heavy chains with λ light chains. The skin changes may consist of hyperpigmentation, hypertrichosis, hyperhidrosis, skin thickening, telangiectasia, and glomeruloid hemangiomas.⁴⁸ Treatment with corticosteroids, low-dose alkylators, and high-dose melphalan and autologous peripheral blood stem cell transplantation has been reported to be successful.^{49,50}

Scleromyxedema

Scleromyxedema is a rare disorder frequently characterized by dysproteinemia and widespread skin changes. The paraprotein has been shown to stimulate fibroblast production of mucin, suggesting a causal role and a rationale for lowering it. Patients have waxy papules on the face, neck, upper trunk, forearms, hands, and thighs that become confluent and occur in association with underlying sclerosis, which can lead to joint contractures, sclerodactyly, and carpal tunnel syndrome. Common extracutaneous manifestations include upper gastrointestinal dysmotility, muscle weakness, joint contractures, and neurologic symptoms such as seizures, encephalopathy, coma, and obstructive or restrictive pulmonary disease. Eighty percent of patients have a monoclonal gammopathy, most frequently IgG- λ , but occasionally IgG- κ .

Skin biopsy shows mucin deposition and a proliferation of fibroblasts in the upper dermis. Treatment has included prednisone, IVIG, PUVA, systemic retinoids, thalidomide, interferon alfa-2a, plasmapheresis, photopheresis, low-dose melphalan, and high-dose dexamethasone.^{51,52}

Chemotherapeutic agents such as melphalan, cyclosporine, cladribine, cyclophosphamide, methotrexate, and chlorambucil have been used. Successful remission after autologous stem cell transplantation has been reported.⁵³

Nephrogenic Systemic Fibrosis

Nephrogenic systemic fibrosis (NSF) is a relatively new illness that occurs in patients with renal disease, with most of the patients having undergone dialysis for renal failure.⁵⁴ NSF presents as either a morphea-like disease or a more diffuse acral sclerosis. Morphea-like presentations include ill-defined indurated plaques, with islands of sparing and finger-like projections that involve lower more than upper extremities. More diffuse confluent acral sclerosis, sometimes with truncal involvement, can occur. There are often yellow plaques on the conjunctiva. Patients can experience pain, severe itching, joint contractures, fibrosis and calcification of the skin, subcutaneous tissue, fascia, muscle, myocardium, lungs, renal tubules, and testes. Patients typically do not have Raynaud's syndrome. Skin biopsy is identical to that seen with scleromyxedema, with stellate fibroblasts, glycosaminoglycans, and thickening of collagen.⁵⁵ TGF- β is increased in lesional skin.⁵⁶ There is no proven effective therapy, and prognosis depends on the extent, rapidity of skin involvement, and severity of the systemic disease.⁵⁶ Treatments that have been reported to potentially help include plasmapheresis, IVIG, immunosuppressives, glucocorticoids, interferon- α , thalidomide, PUVA, UVA1, photopheresis, and imatinib mesylate.^{57,58} Recent studies suggest a strong association of NSF with gadolinium exposure.

PRIMARY NECROTIZING VASCULITIS INVOLVING THE SKIN

In cutaneous diseases, vasculitis is a term typically reserved for lesions characterized by damage to vessel walls and a neutrophilic or granulomatous infiltrate. Classification, pathogenesis, diagnostic evaluation, and therapy are covered elsewhere in the text. In this chapter, the focus is on the skin findings and differential diagnosis. The primary determinant of the appearance is the size of the vessel affected.

Leukocytoclastic Small Vessel Vasculitis and Its Variants

Leukocytoclastic small vessel vasculitis is a rather common condition with characteristic histologic findings of fibrinoid necrosis of vessel walls, a neutrophil-predominant infiltrate, and leukocytoclasia (i.e., fragmented nuclei resulting from degeneration of neutrophils).⁵⁹ In the skin, the vessels involved are in the dermis and damage to these vessels results in lesions of a characteristic size. The lesions are both erythematous and purpuric and are distinctly palpable if there are sufficient numbers of neutrophils in the lesion. On physical examination, it may be helpful to palpate several lesions because it is common for the majority of the lesions to be nonpalpable. The usual diameter of the purpuric papules is about 0.3 to 0.6 cm, although smaller and larger lesions may be observed (Figure 43-13). Discrete lesions

Figure 43-13 Leukocytoclastic vasculitis demonstrating nonblanching, purpuric macules.

have a round shape. The center may look dusky, pustular, or ulcerated, or it may appear as a hemorrhagic vesicle. Larger ulcerations may occur when lesions coalesce. Particularly in larger lesions, the devitalized tissue may be a focus for secondary bacterial infection. Lesions tend to occur in dependent areas. Thus for ambulatory patients, lesions are most numerous on the lower legs. Koebnerization, the appearance of lesions along lines of trauma, such as scratches, is sometimes observed.

As mentioned under the discussion of rheumatoid vasculitis, the differential diagnosis of purpuric or petechial lesions may include stasis dermatitis, Schamburg's purpura, platelet dysfunction, petechial drug eruptions, viral exanthems, emboli, thromboses, and sludging. Skin biopsy is often helpful in establishing the diagnosis of small vessel vasculitis, especially if an early lesion is sampled. Immunofluorescence of an early lesion may establish whether the vasculitis is IgA predominant.

Small vessel vasculitis unassociated with connective tissue disease and not IgA-predominant is sometimes called *hypersensitivity vasculitis*. It is often apparently confined to the skin and therefore has a good prognosis. In some cases, infection or drug may be implicated, but often there is no definitive initiating event discovered. Therapy is directed first toward treating the underlying cause, if a cause is found. If there is no significant extracutaneous disease, treatment is often symptomatic. Leg elevation, compression stockings, and reduction of activity may be helpful. Nonsteroidal anti-inflammatory agents or antihistamines are sometimes used. Systemic corticosteroids are not routinely indicated for skin-limited disease. For patients with persistent disease confined to the skin, colchicine and dapsone have each been used with some success.⁶⁰

A common variant of small vessel vasculitis is Henoch-Schönlein purpura (HS purpura). HS purpura occurs commonly in children and is often associated with extracutaneous findings of gastrointestinal or renal involvement. The typical lesion of IgA-predominant small vessel vasculitis is an erythematous or urticarial macule or papule that evolves rapidly into palpable purpura. It has been noted that IgA-predominant vasculitis in particular may display superficial

plaques of palpable purpura or a retiform configuration of lesions.⁶¹ The most reliable means of establishing that the vasculitis is IgA predominant is biopsy for immunofluorescence. IgA-predominant vasculitis is not unusual in adults. Compared with the presentation in children, there is a lower association with preceding upper respiratory infection and higher association with medication use.

Mixed cryoglobulinemia can present as a small vessel vasculitis. Additional skin findings that may occur include livedo reticularis, urticarial papules, cold urticaria, Raynaud's syndrome, acrocyanosis, leg ulcers, and digital ulceration or gangrene. Hepatitis C is a frequent association. Patients with type I monoclonal cryoglobulinemia may more often have purpura due to cryogelling rather than a true vasculitis.

A distinct subset of patients with small vessel vasculitis has lesions that are primarily urticarial rather than purpuric. The main diagnosis in the clinical differential is urticaria. Individual lesions of urticaria tend to be short-lived, usually less than 24 hours, whereas individual lesions of urticarial vasculitis tend to last several days. Additional skin findings may include angioedema, livedo reticularis, nodules, and bullae. In some lesions, foci of purpura may be observed. Urticarial vasculitis has been classified into two groups: normocomplementemic and hypocomplementemic. Extracutaneous disease is more likely to occur in the hypocomplementemic group, and some of these patients have underlying SLE. It has been proposed that there is a distinctive subset of the hypocomplementemic group characterized by IgG antibodies to C1q, angioedema, ocular inflammation, arthritis, obstructive pulmonary disease, and renal disease. The pulmonary disease tends to be severe and life threatening. This subset has been termed *hypocomplementemic urticarial vasculitis syndrome*.^{62,63}

Erythema elevatum diutinum is an unusual form of small vessel vasculitis that is characterized by erythematous or violaceous papules, plaques, and nodules over the dorsal hands, ears, knees, heel, and buttocks. In the clinical differential diagnosis are Sweet's syndrome, multicentric reticulohistiocytosis, sarcoidosis, and lymphoma, among others. With time, fibrosis often occurs. Established lesions may be disfiguring and may have an appearance somewhat reminiscent of keloids. Although significant extracutaneous involvement is not expected and many patients are otherwise well, erythema elevatum diutinum has been reported in association with various autoimmune, infectious, and hematologic conditions including streptococcal infection, paraproteinemia, inflammatory bowel disease, RA, SLE, and HIV. For active skin lesions, dapsone is the usual treatment.⁶⁴ Intraleisional corticosteroids are sometimes used for fibrotic lesions.

Acute hemorrhagic edema of childhood is an uncommon but generally benign and self-limited form of vasculitis usually occurring in children younger than the age of 2 years, commonly preceded by an upper respiratory infection or medication.⁶⁵ The clinical appearance may be dramatic, with large purpuric plaques on the face, ears, and extremities. On the basis of the appearance of the skin lesions, meningococcemia is sometimes suspected but the child with acute hemorrhagic edema appears relatively healthy. Generally there is no extracutaneous involvement. Treatment is symptomatic.

Granulomatous Vasculitides

Skin lesions are occasionally the presenting feature of granulomatosis with polyangiitis (formerly Wegener's granulomatosis).⁶⁶ The most common type of lesion is palpable purpura, with or without necrosis. Many other types of lesions have been noted including papules, ecchymoses, hemorrhagic bullae, necrotic papules, subcutaneous nodules, and ulcers. Ulcerative lesions may be similar in appearance to pyoderma gangrenosum, although lacking an undermined border. Oral ulcers are relatively common but nonspecific in appearance. A more specific oral finding is hypertrophic gingival inflammation with petechiae.

Skin biopsy is sometimes helpful diagnostically, but unfortunately, biopsies are often nonspecific or show leukocytoclastic vasculitis. True granulomatous vasculitis is not often observed in skin specimens. Extravascular granulomatous inflammation is sometimes noted and may be more likely in nonpurpuric papules or nodules than in palpable purpura.

Differential diagnosis of the skin lesions includes other small vessel vasculitides, particularly when cutaneous lesions consist of palpable purpura and the biopsy finding is leukocytoclastic vasculitis. If granulomatous inflammation is observed, the differential may include Churg-Strauss syndrome, polyarteritis nodosa, microscopic polyangiitis, RA, SLE, infection, lymphoproliferative disorders, chronic active hepatitis, erythema nodosum, granuloma annulare, and inflammatory bowel disease.

Patients with Churg-Strauss syndrome characteristically present with respiratory symptoms, but skin lesions are common during the vasculitic phase of the disease.⁶⁷ Hemorrhagic lesions ranging from petechiae to palpable purpura to ecchymoses, cutaneous nodules with or without ulceration, subcutaneous nodules, and nonspecific erythematous eruptions are most common. As with granulomatosis with polyangiitis, hemorrhagic lesions tend to show small vessel vasculitis on biopsy, and nodules are more likely to demonstrate granulomas. The clinical and histologic differential diagnoses often include polyarteritis nodosa, granulomatosis with polyangiitis, and microscopic polyangiitis. As alluded to earlier, the histologic finding of Churg-Strauss granuloma is not specific for Churg-Strauss and may be seen in several entities. Large numbers of eosinophils in the biopsy may be diagnostically helpful but not definitive. Hypereosinophilic syndrome may share clinical and laboratory features with Churg-Strauss, but vasculitis is not characteristic.

Polyarteritis Nodosa and Related Conditions

Classic polyarteritis nodosa (PAN) and microscopic polyangiitis have historically been classified together as PAN but appear to be distinct conditions distinguishable in part by the size of vessels affected. Classic PAN involves medium-sized vessels, whereas microscopic polyangiitis primarily involves vessels ranging in size from capillaries to arterioles.

Cutaneous findings of classic PAN represent damage downstream of the affected vessel and consist of ulceration, digital gangrene, ecchymoses from vessel rupture, livedo reticularis, and subcutaneous nodules that may follow

the course of arteries. Because the affected vessel is proximal to the skin, skin biopsy is likely to show nonspecific findings.

The skin findings of microscopic polyangiitis reflect the smaller size of vessels affected. Petechiae, palpable purpura, purpuric plaques, erythematous nodules, and ulcerations may be observed. There have been some reports of livedo reticularis in association. The cutaneous pathology is that of a leukocytoclastic vasculitis, but, in contrast to many of the small vessel vasculitides previously discussed, may involve small arterioles. The differential diagnosis is mainly that of other small vessel vasculitides. Size of vessels affected, antineutrophilic cytoplasmic antibody (ANCA) positivity, paucity or absence of antibody deposits in vessels, and spectrum of extracutaneous involvement aid in distinguishing microscopic polyangiitis from other vasculitides.

There is a variant of PAN termed *benign cutaneous PAN* or, perhaps more accurately, *primarily cutaneous PAN*. In this condition, arterioles in the subcutaneous fat and lower dermis are affected, and the presentation is often that of tender subcutaneous nodules and livedo reticularis. Associations with Crohn's disease, hepatitis B, and hepatitis C have been reported. Clinically, panniculitides such as erythema nodosum and erythema induratum may be considered, although livedo reticularis is not expected. Biopsy for diagnosis should include subcutaneous fat. Even after biopsy, microscopic polyangiitis may be difficult to exclude. Although relatively little information is available concerning ANCA in cutaneous PAN, a negative ANCA is more consistent with cutaneous PAN than with microscopic polyangiitis. Although the outcome is benign, the course is often chronic and relapsing. Therapy is typically conservative and may consist of intralesional corticosteroids, nonsteroidal anti-inflammatory agents (NSAIDs), low-dose methotrexate, dapsone, or occasionally systemic corticosteroids.

Kawasaki disease is considered a polyarteritis nodosa variant due to the involvement of coronary arteries. Skin findings constitute several of the criteria for diagnosis. None of the findings is specific for Kawasaki's disease, but the constellation of findings establishes the diagnosis. Kawasaki disease usually affects young children but has been reported in adults. Criteria for diagnosis are otherwise unexplained fever for at least 5 days and four of the following five findings: (1) bilateral nonexudative conjunctivitis; (2) injected pharynx, strawberry tongue, or injected or fissured lips; (3) erythema of palms or soles, hand and foot edema, and, in the convalescent phase, desquamation; (4) erythematous, polymorphous, generalized skin eruption; and (5) cervical lymphadenopathy. In addition, erythema of the perineal region is common and transverse lines across the fingernail beds have been noted in a few cases.

Large Vessel Vasculitis

Skin findings of temporal arteritis (giant cell arteritis) consist mainly of palpable temporal arteries, skin tenderness in the area, and scalp nodules or ulcerations. Skin lesions in patients with Takayasu's arteritis may include Raynaud's phenomenon, livedo reticularis, ulcerated nodules, subcutaneous nodules, and pyoderma gangrenosum-like ulcers. Skin biopsy is generally not performed in these conditions.

INFECTIONS

Many infectious diseases present with both skin and rheumatologic findings.⁶⁸ This section will highlight a few examples.

Lyme Borreliosis

Borrelia burgdorferi, the causative agent of Lyme disease in North America, is associated with erythema migrans (EM). In Europe the related genospecies *Borrelia afzelii* is associated with both erythema migrans and acrodermatitis chronica atrophicans, and several European studies have found compelling evidence for *B. afzelii* infection in patients with morphea. There has been no similar association of *Borrelia* with morphea in the United States.⁶⁹ Hematogenous dissemination from the initial skin site is believed to cause secondary skin lesions and extracutaneous manifestations, and only certain subtypes of *B. burgdorferi* are associated with dissemination.

EM is the first manifestation of Lyme disease in 60% to 80% of people and occurs at the site of the tick bite.⁷⁰ At the time of the skin lesion, which occurs within a few days to a month after the bite, the spirochetes enter the circulation and disseminate. The skin findings may be associated with fever, chills, fatigue, headache, neck stiffness, myalgias, arthralgias, conjunctivitis, erythematous throat, and regional or generalized lymphadenopathy. The lesions of EM begin as red macules that become papular and then expand into an erythematous, annular plaque (Figure 43-14). Two forms of EM exist. In one, there is an expanding red plaque with varying intensities of redness within the plaque. In the second, there is a target, with a central red plaque surrounded by normal-appearing skin, which in turn is surrounded by another band of erythema. They can enlarge rapidly, and multiple lesions due to hematogenous spread are seen 17% of the time. As the lesion enlarges, the central erythema can fade. The central portion of the lesion may be edematous, vesicular, urticarial, or crusted.

Figure 43-14 Lyme disease with characteristic erythematous, annular plaques. (Courtesy Dr. Joshua Levin, University of Pennsylvania Department of Dermatology, Philadelphia.)

Triangular and elongated oval lesions have been described, but circular lesions are most frequent. The most common locations are the inguina, axillae, abdomen, and behind the knees. EM lesions are usually asymptomatic but can be pruritic or painful. Untreated EM lesions resolve in a median of 28 days, with a range from 1 day to 14 months. Resolution is within a few days after treatment with antibiotics such as doxycycline or penicillin.

Acrodermatitis chronica atrophicans (ACA) is associated with late Lyme disease. It occurs mainly in women between ages 40 and 70. The lesions begin on an extremity, usually the lower leg or foot as a bluish-red edematous plaque. Fibrous bands may develop, especially on the ulnar and tibial regions, and fibrous nodules may form near joints. Regional lymphadenopathy is often present. Over many years, the skin becomes atrophic.⁷¹ *B. burgdorferi* has been isolated from the skin of patients with ACA.⁷²

Parvovirus

Presentation of parvovirus B19 includes an erythematous “slapped cheeks” appearance; a lacy, reticulated proximal extremity rash; a febrile petechial eruption; and papular-purpuric gloves and socks syndrome (PPGSS). The infection is self-limited and generally resolves spontaneously within 1 to 2 weeks. Laboratory findings may include mild or severe leukopenia, transient neutropenia or relative neutrophilia, eosinophilia, and mild thrombocytopenia. Adults who are infected often contract the virus from infected children and commonly present with systemic disease including arthropathy and a flulike illness.⁷³

Atypical Infections: *Mycobacterium marinum*

Many types of mycobacteria, atypical mycobacteria, and deep fungal infections can affect skin and joints. *Mycobacterium marinum* is an example and can be acquired through exposure to fresh water, salt water, fish tanks, swimming pools, fish or aquatic exposures, timber cuts, or splinters. The incubation period is usually about 3 weeks, although much longer periods are possible. The disease often occurs after inoculation into abrasions or after penetrating injuries to the fingers and hands. This is an indolent disease, with nodules or ulcerated plaques, occasionally with extension to deep tissue. Common areas of involvement are the fingers, dorsum of the hands, and knees. The lesions can be localized or sporotrichoid (25%), with dissemination 2% of the time.

PANNICULITIS

Panniculitis refers to a group of diseases that manifest as inflammation or alterations in the subcutaneous fat. The complexity of etiologies for even one form of panniculitis such as erythema nodosum, the relative rarity of most forms of panniculitis, and the number of different panniculitides has slowed the scientific development. The etiologies for many panniculitides are still poorly understood.

Panniculitis may be primary without an identifiable cause or secondary. Common secondary causes of panniculitis include infection, trauma, pancreatic disease, immunodeficiency states, malignancies, and connective tissue
